src1 ← bfp_CONVERT_FROM_BFP128(VSR[VRA+32])
src2 ← bfp_CONVERT_FROM_BFP128(VSR[VRB+32])
v ← bfp_ADD(src1, bfp_NEGATE(src2))
rnd ← bfp_ROUND_TO_BFP128(RD, FPSCR.RN, v)
result ← bfp128_CONVERT_FROM_BFP(rnd)

if vxsnan_flag=1 then SetFX(FPSCR.VXSNAN)
if vxisi_flag=1 then SetFX(FPSCR.VXISI)
if ox_flag=1 then SetFX(FPSCR.OX)
if ux_flag=1 then SetFX(FPSCR.UX)
if xx_flag=1 then SetFX(FPSCR.XX)

vx_flag ← vxsnan_flag | vxisi_flag
vex_flag ← FPSCR.VE & vx_flag

if vex_flag=0 then do
VSR[VRT+32] ← result
FPSCR.FPRF ← fprf_CLASS_BFP128(result)
end
FPSCR.FR ← (vx_flag=0) & inc_flag
FPSCR.FI ← (vx_flag=0) & xx_flag

Let src1 be the floating-point value in VSR[VRA+32] represented in quad-precision format.

Let src2 be the floating-point value in VSR[VRB+32] represented in quad-precision format.

If either src1 or src2 is a Signalling NaN, an Invalid Operation exception occurs and VXSNAN is set to 1.

If src1 and src2 are Infinity values having same signs, an Invalid Operation exception occurs and VXISI is set to 1.

If src1 is a Signalling NaN, the result is the Quiet NaN corresponding to src1.

Otherwise, if src1 is a Quiet NaN, the result is src1.

Otherwise, if src2 is a Signalling NaN, the result is the Quiet NaN corresponding to src2.

Otherwise, if src2 is a Quiet NaN, the result is src2.

Otherwise, if src1 and src2 are Infinity values having same signs, the result is the default Quiet NaN[1].

Otherwise, do the following.

The normalized sum of the negation of src2 added to src1 is produced with unbounded significand precision and exponent range.

See Table 111, “Actions for xssubq[0],” on page 810.

If the intermediate result is Tiny (i.e., the unbiased exponent is less than -16382) and UE=0, the significand is shifted right \(N\) bits, where \(N\) is the difference between -16382 and the unbiased exponent of the intermediate result. The exponent of the intermediate result is set to the value -16382.

If RO=1, let the rounding mode be Round to Odd. Otherwise, let the rounding mode be specified by RN. Unless the result is an Infinity or a Zero, the intermediate result is rounded to quad-precision using the specified rounding mode.

The result is placed into VSR[VRT+32] in quad-precision format.

FPRF is set to the class and sign of the result. FR is set to indicate if the rounded result was incremented. FI is set to indicate the result is inexact.

If a trap-disabled Invalid Operation exception occurs, FPRF is set to an undefined value, and FR and FI are set to 0.

If a trap-enabled Invalid Operation exception occurs, VSR[VRT+32] and FPRF are not modified, and FR and FI are set to 0.

See Table 63, “VSX Scalar Floating-Point Final Result,” on page 662.

Special Registers Altered:

FPRF FR FI FX VXSNAN VXISI OX UX XX

```

### Explanation

Let $src2$ be the double-precision floating-point value in doubleword element 0 of $VSR[XB]$.

$src2$ is negated and added$^{[1]}$ to $src1$, producing the sum, $v$, having unbounded range and precision.

See Table 112, "Actions for xssubsp," on page 812. $v$ is normalized$^{[2]}$ and rounded to single-precision using the rounding mode specified by $RN$.

The result is placed into doubleword element 0 of $VSR[XT]$.

The contents of doubleword element 1 of $VSR[XT]$ are set to 0.

$FPRF$ is set to the class and sign of the result as represented in single-precision format. $FR$ is set to indicate if the result was incremented when rounded. $FI$ is set to indicate the result is inexact.

If a trap-enabled invalid operation exception occurs, $VSR[XT]$ and $FPRF$ are not modified, and $FR$ and $FI$ are set to 0.

See Table 63, "VSX Scalar Floating-Point Final Result," on page 662.

### Special Registers Altered

- $FPFR$  
- $FR$  
- $FI$  
- $FX$  
- $OX$  
- $UX$  
- $XX$  
- $VXSNAN$  
- $VXSI$

### Programming Note

Previous versions of the architecture allowed the contents of doubleword 1 of the result register to be undefined. However, all processors that support this instruction write 0s into doubleword 1 of the result register, as is required by this version of the architecture.

### VSR Data Layout for xssubsp

  - $VSR[XB].dword[0]$  
  - $0x0000_0000_0000_0000$

1. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.

2. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.
### Explanation:

- **src1**: The double-precision floating-point value in doubleword element 0 of VSR[XA].
- **src2**: The double-precision floating-point value in doubleword element 0 of VSR[XB].
- **dQNaN**: Default quiet NaN (0x7FF8_0000_0000_0000).
- **NZF**: Nonzero finite number.
- **Rezd**: Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs).
- **S(x,y)**: The floating-point value y is negated and then added to the floating-point value x.
- **S(x,y)**: Return the normalized sum of floating-point value x and negated floating-point value y, having unbounded range and precision.
  - **Note**: If x = y, v is considered to be an exact-zero-difference result (Rezd).
- **Q(x)**: Return a QNaN with the payload of x.
- **v**: The intermediate result having unbounded significand precision and unbounded exponent range.

\]

Let XT be the value \(32 \times TX + T\).
Let XA be the value \(32 \times AX + A\).
Let XB be the value \(32 \times BX + B\).

For each integer value \(i\) from 0 to 1, do the following.

Let \(s_{rc1}\) be the double-precision floating-point operand in doubleword element \(i\) of VSR[XA].

Let \(s_{rc2}\) be the double-precision floating-point operand in doubleword element \(i\) of VSR[XB].

\(s_{rc2}\) is added \(^1\) to \(s_{rc1}\), producing a sum having unbounded range and precision.

The sum is normalized \(^2\).

See Table 113.

The intermediate result is rounded to double-precision using the rounding mode specified by RN.

The result is placed into doubleword element \(i\) of VSR[XT] in double-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 823.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

**Special Registers Altered**

\[
\text{FX OX UX XX VXSNAN VXISI}
\]

---

1. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.

2. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

### Explanation:
- The results do not depend on this condition.
- f(x) The value defined in Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 661, significand rounded to the target precision, unbounded exponent range.
- q The precise intermediate result defined in the instruction having unbounded significand precision, unbounded exponent range.
- r The value defined in Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 661, significand rounded to the target precision, bounded exponent range.
- The system error handler is invoked for the trap-enabled exception if MSR.FE0 and MSR.FE1 bits are set to any mode other than the ignore-exception mode. Update of the target VSR is suppressed for all vector elements.
- T(x) The value x is placed in element i of VSR[XT] in the target precision format (where i = {0, 1} for results with 64-bit elements, and i = {0, 1, 3, 4} for results with 32-bit elements).

Table 114.Vector Floating-Point Final Result
The results do not depend on this condition.

\[ f_x(x) \]  FPSCR.FX is set to \( 1 \) if FPSCR.x = 0. FPSCR.x is set to 1.

\[ t \]  The value defined in Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 661, significand rounded to the target precision, unbounded exponent range.

\[ r \]  The value defined in Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 661, significand rounded to the target precision, bounded exponent range.

\[ v \]  The precise intermediate result defined in the instruction having unbounded significand precision, unbounded exponent range.

\[ \text{error}() \]  The system error handler is invoked for the trap-enabled exception if MSR.FE0 and MSR.FE1 bits are set to any mode other than the ignore-exception mode. Update of the target VSR is suppressed for all vector elements.

\[ T(x) \]  The value \( x \) is placed in element \( i \) of VSR[XI] in the target precision format (where \( i = \{0,1\} \) for results with 64-bit elements, and \( i = \{0,1,3,4\} \) for results with 32-bit elements).

Special Registers Altered

FX OX UX XX VXSNAN VXISI

Let XT be the value \(32\times TX + T\).
Let XA be the value \(32\times AX + A\).
Let XB be the value \(32\times BX + B\).

For each integer value \(i\) from 0 to 3, do the following.

Let \(\text{src1}\) be the single-precision floating-point operand in word element \(i\) of VSR[XA].

Let \(\text{src2}\) be the single-precision floating-point operand in word element \(i\) of VSR[XB].

\(\text{src2}\) is added\(^1\) to \(\text{src1}\), producing a sum having unbounded range and precision.

The sum is normalized\(^2\).

See Table 115.

The intermediate result is rounded to single-precision using the rounding mode specified by RN.

The result is placed into word element \(i\) of VSR[XT] in single-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 823.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

VSR Data Layout for xvaddsp

|------|----------------|----------------|----------------|----------------|

---

1. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the sign of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.

2. Floating-point normalization is based on shifting the significant left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

Let \( X_A \) be the value of \( 32 \times X_A + A \). If \( X_A \) is in the range \( 4 \times AT \) to \( 4 \times AT + 3 \), the instruction form is invalid.

Let \( X_B \) be the value of \( 32 \times X_B + B \). If \( X_B \) is in the range \( 4 \times AT \) to \( 4 \times AT + 3 \), the instruction form is invalid.

Let the contents of \( ACC[AT] \) be a \( 4 \times 4 \) matrix of single-precision floating-point values.

For \( xvbf16ger2 \), \( xvbf16ger2pp \), \( xvbf16ger2pn \), \( xvbf16ger2np \), or \( xvbf16ger2nn \), let \( PMSK = 0b11 \), \( XMSK = 0b1111 \), and \( YMSK = 0b1111 \).

For each integer value \( i \) from 0 to 3, and each integer value \( j \) from 0 to 3, do the following.

If bit \( i \) of \( XMSK \) is equal to 1 and bit \( j \) of \( YMSK \) is equal to 1, do the following.

If bit 0 of \( PMSK \) is equal to 1, let \( src10 \) be the bfloat16 floating-point value in halfword 0 of word element \( i \) of \( VSR[XA] \) and let \( src20 \) be the bfloat16 floating-point value in halfword 0 of word element \( j \) of \( VSR[XB] \). Otherwise, let \( src10 \) be the value 0.0 and let \( src20 \) be the value 0.0, causing the product of \( src10 \) and \( src20 \) to be 0.0.

If bit 1 of \( PMSK \) is equal to 1, let \( src11 \) be the bfloat16 floating-point value in halfword 1 of word element \( i \) of \( VSR[XA] \) and let \( src21 \) be the bfloat16 floating-point value in halfword 1 of word element \( j \) of \( VSR[XB] \). Otherwise, let \( src11 \) be the value 0.0 and let \( src21 \) be the value 0.0, causing the product of \( src11 \) and \( src21 \) to be 0.0.

Let \( prod \) be the product of \( src10 \) and \( src20 \), having infinite precision and unbounded exponent range.

Let \( psum \) be the sum of the product, \( src11 \) multiplied by \( src21 \), and \( prod \), having infinite precision and unbounded exponent range.

Let \( r1 \) be the value \( psum \) with its significand rounded to 24-bit precision using the rounding mode specified by \( RN \), but retaining unbounded exponent range (i.e., cannot overflow or underflow).

For \( [pm]xvbf16ger2 \), do the following.

Let \( r2 \) be the value \( r1 \) rounded to 24-bit significand precision and 8-bit exponent range (i.e., single-precision) using the rounding mode specified by \( RN \).

\( r2 \) is placed into word element \( j \) of \( ACC[AT][i] \) in single-precision floating-point format.

For \( [pm]xvbf16ger2pp \), do the following.

Let \( r2 \) be the sum of \( r1 \) added to the single-precision floating-point value in word element \( j \) of \( ACC[AT][i] \), having infinite precision and unbounded exponent range.

Let \( r2 \) be the value \( v2 \) rounded to 24-bit significand precision and 8-bit exponent range (i.e., single-precision) using the rounding mode specified by \( RN \).

\( r2 \) is placed into word element \( j \) of \( ACC[AT][i] \) in single-precision floating-point format.

For \( [pm]xvbf16ger2pn \), do the following.

Let \( r2 \) be the sum of the negation of \( r2 \) added to the negation of the single-precision floating-point value in word element \( j \) of \( ACC[AT][i] \), having infinite precision and unbounded exponent range.

Let \( r2 \) be the value \( v2 \) rounded to 24-bit significand precision and 8-bit exponent range (i.e., single-precision) using the rounding mode specified by \( RN \).

\( r2 \) is placed into word element \( j \) of \( ACC[AT][i] \) in single-precision floating-point format.

For \( [pm]xvbf16ger2np \), do the following.

Let \( v2 \) be the sum of the negation of \( r2 \) added to the single-precision floating-point value in word element \( j \) of \( ACC[AT][i] \), having infinite precision and unbounded exponent range.

Let \( r3 \) be the value \( v3 \) rounded to 24-bit significand precision and 8-bit exponent range (i.e., single-precision) using the rounding mode specified by \( RN \).

\( r2 \) is placed into word element \( j \) of \( ACC[AT][i] \) in single-precision floating-point format.
For \([pm]\text{xvbf16ger2nn}\), do the following.

Let \(v_2\) be the sum of the negation of \(r_2\) added to the negation of the single-precision floating-point value in word element \(j\) of \(\text{ACC}[\text{AT}][i]\), having infinite precision and unbounded exponent range.

Let \(r_2\) be the value \(v_3\) rounded to 24-bit significand precision and 8-bit exponent range (i.e., single-precision) using the rounding mode specified by \(\text{RN}\).

\(r_2\) is placed into word element \(j\) of \(\text{ACC}[\text{AT}][i]\) in single-precision floating-point format.

Otherwise, the contents of word element \(j\) of \(\text{ACC}[\text{AT}][i]\) are set to \(0x0000_0000\).

Unlike other VSX Vector Floating-Point instructions, \(\text{ACC}[\text{AT}]\) is always updated by the execution of the instruction, even when a trap-enabled exception occurs. For every rounding operation that is performed as part of the execution of this instruction, if an exception occurs as the result of that particular rounding operation, the trap-disabled exception result is returned, even if that exception type is trap-enabled. Exception detection is based on the trap-disabled definition. Exception status is accumulated and the appropriate exception status bits in the FPSCR are updated at the completion of execution of the instruction. Otherwise, behavior is the same as any vector floating-point instruction that can cause an exception. Taking a Program interrupt on a trap-enabled exception when interrupts are enabled by MSR.FE0 and MSR.FE1 is still supported, albeit with the \(\text{ACC}[\text{AT}]\) updated based on a trap-disabled result.

tgt VSR[XT].dword[0] VSR[XT].dword[1]
**VSX Vector Compare Greater Than or Equal To Single-Precision XX3-form**

\[
\text{xvcmpgesp}: \quad XT,XA,XB \quad (Rc=0) \\
\text{xvcmpgesp}: \quad XT,XA,XB \quad (Rc=1)
\]

Let \( XT \) be the value \( 32 \times TX + T \).  
Let \( XA \) be the value \( 32 \times AX + A \).  
Let \( XB \) be the value \( 32 \times BX + B \).

For each integer value \( i \) from 0 to 3, do the following.

Let \( src1 \) be the single-precision floating-point operand in word element \( i \) of \( VSR[XA] \).

Let \( src2 \) be the single-precision floating-point operand in word element \( i \) of \( VSR[XB] \).

\( src1 \) is compared to \( src2 \).

The contents of word element \( i \) of \( VSR[XT] \) are set to all 1s if \( src1 \) is greater than or equal to \( src2 \), and is set to all 0s otherwise.

A NaN input causes the comparison to return false for that element.

Two zero inputs of same or different signs return true for that element.

Two infinity inputs of same signs return true for that element.

If \( Rc=1 \), CR Field 6 is set as follows.

- Bit 0 is set to indicate all vector elements compared true.
- Bit 1 is set to 0.
- Bit 2 is set to indicate all vector elements compared false.
- Bit 3 is set to 0.

If a trap-enabled exception occurs in any element of the vector, no results are written to \( VSR[XT] \) and the contents of CR field 6 are undefined if \( Rc \) is equal to 1.

Let XT be the value $32 \times TX + T$.
Let XB be the value $32 \times BX + B$.

For each integer value $i$ from 0 to 1, do the following.

Let src be the double-precision floating-point operand in doubleword element $i$ of VSR[XB].

src is rounded to single-precision using the rounding mode specified by RN.

The result is placed into bits 0:31 and bits 32:63 of doubleword element $i$ of VSR[XT] in single-precision format.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

### Special Registers Altered

FX OX UX XX VXSNAN

### Programming Note

Previous versions of the architecture allowed the contents of bits 32:63 of each doubleword in the result register to be undefined, however, all processors that support this instruction write the result into bits 32:63 of each doubleword in the result register as well as into bits 0:31, as is required by this version of the architecture.

### Programming Note

Previous versions of the architecture allowed the contents of doubleword 1 of the result register to be undefined. However, all processors that support this instruction write 0s into doubleword 1 of the result register, as is required by this version of the architecture.

- \( \text{rnd} \leftarrow \text{bfp\_ROUND\_TO\_INTEGER\_TRUNC(src)} \)
- \( \text{vresult.dword[i].word[0]} \leftarrow \text{ui32\_CONVERT\_FROM\_BFP(rnd)} \)
- \( \text{vresult.dword[i].word[1]} \leftarrow \text{ui32\_CONVERT\_FROM\_BFP(rnd)} \)
- \( \text{if vxsnan\_flag=1 then SetFX(FPSCR.VXSNAN)} \)
- \( \text{if vxcvi\_flag=1 then SetFX(FPSCR.VXCVI)} \)
- \( \text{if xx\_flag=1 then SetFX(FPSCR.XX)} \)
- \( \text{ex\_flag} \leftarrow \text{ex\_flag} | (FPSCR.VE \& vxsnan\_flag) \)
- \( \quad | (FPSCR.VE \& vxcvi\_flag) \)
- \( \quad | (FPSCR.XE \& xx\_flag) \)
- \( \text{end} \)
- \( \text{if ex\_flag=0 then VSR[32\times TX+T] \leftarrow \text{vresult}} \)

Let \( \text{XT} \) be the value \( 32\times TX + T \).

Let \( \text{XB} \) be the value \( 32\times BX + B \).

For each integer value \( i \) from 0 to 1, do the following.

Let \( \text{src} \) be the double-precision floating-point operand in doubleword element \( i \) of VSR[XB].

- If \( \text{src} \) is a NaN, the result is the value \( 0x8000_0000 \) and VXCVI is set to 1. If \( \text{src} \) is an SNaN, VXSNAN is also set to 1.

Otherwise, \( \text{src} \) is rounded to a floating-point integer using the rounding mode Round Toward Zero.

If the rounded value is greater than \( 2^{32}-1 \), the result is \( 0xFFFF_FFFF \) and VXCVI is set to 1.

Otherwise, if the rounded value is less than 0, the result is \( 0x0000_0000 \) and VXCVI is set to 1.

Otherwise, the result is the rounded value converted to 32-bit unsigned-integer format, and if the result is inexact (i.e., not equal to \( \text{src} \)), XX is set to 1.

The result is placed into bits 0:31 of doubleword element \( i \) of VSR[XT].

The result is also placed into bits 32:63 of doubleword element \( i \) of VSR[XT].

See Table 119.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

#### Special Registers Altered

FX XX VXSNAN VXCVI

---

**Programming Note**

\( \text{xvcvdpuxws} \) rounds using Round towards Zero rounding mode. For other rounding modes, software must use a Round to Double-Precision Integer instruction that corresponds to the desired rounding mode, including \( \text{xvrdpic} \) which uses the rounding mode specified by RN.

---

**Programming Note**

Previous versions of the architecture allowed the contents of words 1 and 3 of the result register to be undefined. However, all processors that support this instruction write the result into words 0 and 1 and words 2 and 3 of the result register, as is required by this version of the architecture.

---

Explanation:

- error() The system error handler is invoked for the trap-enabled exception if MSR.FE0 and MSR.FE1 are set to any mode other than the ignore-exception mode.
- Update of VSR[XT] is suppressed.
- \( f2i(x) \) The double-precision floating-point integer value \( x \) is converted to 32-bit unsigned integer format.
- \( fx(x) \) FPSCR.FX is set to 1 if FPSCR.x=0. FPSCR.x is set to 1.
- \( N_{\text{min}} \) The smallest unsigned integer word value, \( 0 (0x0000_0000) \).
- \( N_{\text{max}} \) The largest unsigned integer word value, \( 2^{32} - 1 (0xFFFF_FFFF) \).
- \( src \) The double-precision floating-point value \( x \) is placed in word elements \( 2^i \) and \( 2^i+1 \) of VSR[XT] (where \( i = 0, 1 \)).
- \( T(x) \) The double-precision floating-point value \( x \) is truncated to a floating-point integer.
VSX Vector Convert bfloat16 to Single-Precision format XX2-form

Let \(\text{XT}\) be the value \(32 \times \text{T} + T\).
Let \(\text{XB}\) be the value \(32 \times \text{BX} + B\).

For each integer value \(i\) from 0 to 3, do the following.
Let \(\text{src}\) be the half-precision floating-point value in the rightmost halfword of word element \(i\) of \(\text{VSR[XB]}\).

- If \(\text{src}\) is an SNaN, the result is the single-precision representation of that SNaN converted to a QNaN.
- Otherwise, if \(\text{src}\) is a QNaN, the result is the single-precision representation of that QNaN.
- Otherwise, if \(\text{src}\) is an Infinity, the result is the single-precision representation of Infinity with the same sign as \(\text{src}\).
- Otherwise, if \(\text{src}\) is a Zero, the result is the single-precision representation of Zero with the same sign as \(\text{src}\).
- Otherwise, if \(\text{src}\) is a denormal value, the result is the normalized single-precision representation of \(\text{src}\).
- Otherwise, the result is the single-precision representation of \(\text{src}\).

The result is placed into word element \(i\) of \(\text{VSR[XT]}\).

If a trap-enabled exception occurs, \(\text{VSR[XT]}\) is not modified.

Otherwise, $src$ is rounded to a floating-point integer using the rounding mode Round Toward Zero.

If the rounded value is greater than $2^{64}-1$, the result is $0xFFFFFFFF_FFFF_FFFF_FFFF$ and VXCVI is set to 1.

Otherwise, if the rounded value is less than 0, the result is $0x0000_0000_0000_0000$ and VXCVI is set to 1.

Otherwise, the result is the rounded value converted to 64-bit unsigned-integer format, and if the result is inexact (i.e., not equal to $src$), XX is set to 1.

The result is placed into doubleword element $i$ of $VSR[XT]$.

See Table 119.

If a trap-enabled exception occurs in any element of the vector, no results are written to $VSR[XT]$.

**Special Registers Altered**

FX XX VXSNAN VXCVI

### Programming Note
**xvcvspuxds** rounds using Round towards Zero rounding mode. For other rounding modes, software must use a *Round to Single-Precision Integer* instruction that corresponds to the desired rounding mode, including *xvrsptic* which uses the rounding mode specified by RN.

**Explanation:**

- **error()**
  - The system error handler is invoked for the trap-enabled exception if MSR.FE0 and MSR.FE1 are set to any mode other than the ignore-exception mode.
  - Update of VSR[XT] is suppressed.
- **f2i(x)**
  - The single-precision floating-point integer value x is converted to 64-bit unsigned integer format.
- **fx(x)**
  - FPSCR.fx is set to 1 if FPSCR.x=0. FPSCR.x is set to 1.
- **Nmin**
  - The smallest unsigned integer doubleword value, 0 (0x0000_0000_0000_0000).
- **Nmax**
  - The largest unsigned integer doubleword value, 2^N-1 (0xFFFF_FFFF_FFFF_FFFF).
- **src**
  - The single-precision floating-point value in word element i of VSR[XB] (where i={0,2}).
- **T(x)**
  - The unsigned integer doubleword value x is placed in doubleword element i of VSR[XT] (where i={0,1}).
- **trunc(x)**
  - The single-precision floating-point value i is truncated to a floating-point integer.

### Table 122. Actions for xvcvspuxds
**VSX Vector Convert with round to zero**  
**Single-Precision to Unsigned Word format**  
**XX2-form**

Let $XT$ be the value $32 \times TX + T$.  
Let $XB$ be the value $32 \times BX + B$.

For each integer value $i$ from 0 to 3, do the following.  
Let $src$ be the single-precision floating-point operand in word element $i$ of $VSR[XB]$.

If $src$ is a NaN, the result is the value $0x0000_0000$ and $VXCVI$ is set to 1. If $src$ is an SNaN, $VXSNAN$ is also set to 1.

Otherwise, $src$ is rounded to a floating-point integer using the rounding mode Round Toward Zero.

If the rounded value is greater than $2^{32} - 1$, the result is $0xFFFF_{FFFF}$ and $VXCVI$ is set to 1.

Otherwise, if the rounded value is less than 0, the result is $0x0000_0000$ and $VXCVI$ is set to 1.

Otherwise, the result is the rounded value converted to 32-bit unsigned-integral format, and if the result is inexact (i.e., not equal to $src$), $XX$ is set to 1.

The result is placed into word element $i$ of $VSR[XT]$.

See Table 119.

If a trap-enabled exception occurs in any element of the vector, no results are written to $VSR[XT]$.

FX OX UX ZX XX VXSNAN VXIDI VXZDZ

Let XT be the value 32×TX + T.
Let XA be the value 32×AX + A.
Let XB be the value 32×BX + B.

For each integer value i from 0 to 1, do the following.

Let src1 be the double-precision floating-point operand in doubleword element i of VSR[XA].

Let src2 be the double-precision floating-point operand in doubleword element i of VSR[XB].

src1 is divided[1] by src2, producing a quotient having unbounded range and precision.

The quotient is normalized[2].

See Table 124.

The intermediate result is rounded to double-precision using the rounding mode specified by RN.

The result is placed into doubleword element i of VSR[XT] in double-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 823.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

Special Registers Altered

FX OX UX ZX XX VXSNAN VXIDI VXZDZ

1. Floating-point division is based on exponent subtraction and division of the significands.
2. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.
### Explanation:

- **src1**: The double-precision floating-point value in doubleword element \( i \) of \( \text{VSR}[X_A] \) (where \( i = \{0, 1\} \)).
- **src2**: The double-precision floating-point value in doubleword element \( j \) of \( \text{VSR}[X_B] \) (where \( j = \{0, 1\} \)).
- **dQNaN**: Default quiet NaN (0x7FF8_0000_0000_0000).
- **NZF**: Nonzero finite number.
- **Rezd**: Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs).
- **D(x,y)**: Return the normalized quotient of floating-point value \( x \) divided by floating-point value \( y \), having unbounded range and precision.
- **Q(x)**: Return a QNaN with the payload of \( x \).
- **v**: The intermediate result having unbounded significand precision and unbounded exponent range.

For each integer value \texttt{i} from 0 to 3, do the following.
Let \texttt{src1} be the single-precision floating-point operand in word element \texttt{i} of \texttt{VSR[\texttt{XA}]}.
Let \texttt{src2} be the single-precision floating-point operand in word element \texttt{i} of \texttt{VSR[\texttt{XB}]}.
\texttt{src1} is divided\textsuperscript{1} by \texttt{src2}, producing a quotient having unbounded range and precision.
The quotient is normalized\textsuperscript{2}.
See Table 125.
The intermediate result is rounded to single-precision using the rounding mode specified by \texttt{RN}.
The result is placed into word element \texttt{i} of \texttt{VSR[\texttt{XT}]} in single-precision format.
See Table 114, “Vector Floating-Point Final Result,” on page 823.
If a trap-enabled exception occurs in any element of the vector, no results are written to \texttt{VSR[\texttt{XT}]}.

Special Registers Altered
\texttt{FX OX UX ZX XX VXSNAN VXIDI VXZDZ}

---

1. Floating-point division is based on exponent subtraction and division of the significands.
2. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

Explanation:
- **src1** The single-precision floating-point value in word element \( i \) of VSR[XA] (where \( i = \{0, 1, 2, 3\} \)).
- **src2** The single-precision floating-point value in word element \( j \) of VSR[XB] (where \( j = \{0, 1, 2, 3\} \)).
- **dQNaN** Default quiet NaN (0x7FC0_0000).
- **NZF** Nonzero finite number.
- **Rezd** Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs).
- **D(x,y)** Return the normalized quotient of floating-point value \( x \) divided by floating-point value \( y \), having unbounded range and precision.
- **Note:** If \( x = -y \), \( v \) is considered to be an exact-zero-difference result (Rezd).
- **Q(x)** Return a QNaN with the payload of \( x \).
- **v** The intermediate result having unbounded significand precision and unbounded exponent range.

end

Let XA be the value of 32×AX + A. If XA is in the range 4×AT to 4×AT+3, the instruction form is invalid.
Let XB be the value of 32×BX + B. If XB is in the range 4×AT to 4×AT+3, the instruction form is invalid.

Let the contents of ACC[AT] be a 4×4 matrix of single-precision floating-point values.

Let result be a 4×4 matrix of word elements to be used as a temporary Accumulator.
For \texttt{xfv16ger2}, \texttt{xfv16ger2pp}, \texttt{xfv16ger2pn}, \texttt{xfv16ger2np}, or \texttt{xfv16ger2nn}, let \texttt{PMSK=0b11}, \texttt{XMSK=0b1111}, and 
\texttt{YMSK=0b1111}.

For each integer value \(i\) from 0 to 3, and each integer value \(j\) from 0 to 3, do the following.
If bit \(i\) of \texttt{XMSK} is equal to 1 and bit \(j\) of \texttt{YMSK} is equal to 1, do the following.
If bit 0 of \texttt{PMSK} is equal to 1, let \texttt{src10} be the half-precision floating-point value in hword 0 of word element \(i\) of \texttt{VSR[XA]} and let \texttt{src20} be the half-precision floating-point value in hword 0 of word element \(j\) of \texttt{VSR[XB]}. Otherwise, let \texttt{src10} be the value 0.0 and let \texttt{src20} be the value 0.0, causing the product of \texttt{src10} and \texttt{src20} to be 0.0.

If bit 1 of \texttt{PMSK} is equal to 1, let \texttt{src11} be the half-precision floating-point value in hword 1 of word element \(i\) of \texttt{VSR[XA]} and let \texttt{src21} be the half-precision floating-point value in hword 1 of word element \(j\) of \texttt{VSR[XB]}. Otherwise, let \texttt{src11} be the value 0.0 and let \texttt{src21} be the value 0.0, causing the product of \texttt{src11} and \texttt{src21} to be 0.0.

Let \texttt{prod} be the single-precision product of \texttt{src10} and \texttt{src20}.
Let \texttt{msum} be the sum of \texttt{prod} added to the product of \texttt{src11} and \texttt{src21}. \texttt{msum} is rounded to single-precision using the rounding mode specified in \texttt{RN}.

For \texttt{[pm]xfv16ger2}, the rounded \texttt{msum} is placed into word element \(j\) of \texttt{ACC[AT][i]} in single-precision floating-point format.

For \texttt{[pm]xfv16ger2pp}, the rounded \texttt{msum} is added to the single-precision floating-point value in word element \(j\) of \texttt{ACC[AT][i]}, rounded to single-precision using the rounding mode specified in \texttt{RN}, and placed into word element \(j\) of \texttt{ACC[AT][i]} in single-precision floating-point format.

For \texttt{[pm]xfv16ger2pn}, the rounded \texttt{msum} is added to the negation of the single-precision floating-point value in word element \(j\) of \texttt{ACC[AT][i]}, rounded to single-precision using the rounding mode specified in \texttt{RN}, and placed into word element \(j\) of \texttt{ACC[AT][i]} in single-precision floating-point format.

For \texttt{[pm]xfv16ger2np}, the negation of the rounded \texttt{msum} is added to the single-precision floating-point value in word element \(j\) of \texttt{ACC[AT][i]}, rounded to single-precision using the rounding mode specified in \texttt{RN}, and placed into word element \(j\) of \texttt{ACC[AT][i]} in single-precision floating-point format.

For \texttt{[pm]xfv16ger2nn}, the negation of the rounded \texttt{msum} is added to the negation of the single-precision floating-point value in word element \(j\) of \texttt{ACC[AT][i]}, rounded to single-precision using the rounding mode specified in \texttt{RN}, and placed into word element \(j\) of \texttt{ACC[AT][i]} in single-precision floating-point format.

Otherwise, the contents of \texttt{ACC[AT][i][j]} are set to 0x0000_0000.

Unlike other \textit{VSX Vector Floating-Point} instructions, \texttt{ACC[AT]} is always updated by the execution of the instruction, even when a trap-enabled exception occurs. For every multiply-add operation that is performed as part of the execution of this instruction, if an exception occurs as the result of that particular multiply-add operation, the trap-disabled exception result is returned, even if that exception type is trap-enabled. Exception detection is based on the trap-disabled definition. Exception status is accumulated and the appropriate exception status bits in the \texttt{FPSCR} are updated at the completion of execution of the instruction. Otherwise, behavior is the same as any vector floating-point instruction that can cause an exception. Taking a Program interrupt on a trap-enabled exception when interrupts are enabled by \texttt{MSR.PE0} and \texttt{MSR.PE1} is still supported, albeit with the \texttt{ACC[AT]} updated based on a trap-disabled result.

**Programming Note**

Let \(X\) be the \(4\times2\) matrix of half-precision floating-point values contained in \(VSR[XA]\) in row-major format.
Let \(Y\) be the \(4\times2\) matrix of half-precision floating-point values contained in \(VSR[XB]\) in row-major format.
Let \(ACC[AT]\) be the Accumulator containing a \(4\times4\) matrix of single-precision floating-point values.

Note that floating-point arithmetic is not associative. That is, \((X+Y)+T\) can return a different result than \(X+(Y+T)\).
The ordering specified by the instruction description for any result element \(i,j\) is the order the operations will be performed in hardware. The floating-point operations to implement each result element for \([pm]xvf16ger2[pp|pn|np|nn]\) are shown below.

\([pm]xvf16ger2\) performs the following form of accumulation of two outer products (rank 2 update).

\[
\text{for } i=0 \text{ to } 3, j=0 \text{ to } 3: \\
\quad \text{ACC}[AT][i][j] = \text{fmadds}(X[i][1], Y[j][1], \text{fmuls}(X[i][0], Y[j][0]))
\]

\([pm]xvf16ger2pp\) performs the following form of accumulation of two outer products (rank 2 update).

\[

        if vxisi_flag=1 then SetFX(FPSCR.VXISI)
        if ox_flag=1 then SetFX(FPSCR.OX)
        if ux_flag=1 then SetFX(FPSCR.UX)
        if xx_flag=1 then SetFX(FPSCR.XX)
    end
    else
        ACC[AT][i].word[j] ← 0x0000_0000
    end
end

Let XA be the value of 32×AX + A. If XA is in the range 4×AT to 4×AT+3, the instruction form is invalid.
Let XB be the value of 32×BX + B. If XB is in the range 4×AT to 4×AT+3, the instruction form is invalid.

Let the contents of ACC[AT] be a 4×4 matrix of single-precision floating-point values.

For xvf32ger, xvf32gerpp, xvf32gerpn, xvf32gernp, or xvf32gernn, let XMSK=0b1111 and YMSK=0b1111.

For each integer value i from 0 to 3, and each integer value j from 0 to 3, do the following.
    If bit i of XMSK is equal to 1 and bit j of YMSK is equal to 1, do the following.
        Let prod be the product of the single-precision floating-point value in word element i of VSR[XA] and the single-precision floating-point value in word element j of VSR[XB], having unbounded range and precision.
        For [pm]xvf32ger, prod is rounded to single-precision using the rounding mode specified in RN. The rounded result is placed into word element j of ACC[AT][i] in single-precision floating-point format.
        For [pm]xvf32gerpp, the single-precision floating-point value in word element j of ACC[AT][i] is added to prod. The intermediate result is rounded to single-precision using the rounding mode specified in RN. The rounded result is placed into word element j of ACC[AT][i] in single-precision floating-point format.
        For [pm]xvf32gerpn, the single-precision floating-point value in word element j of ACC[AT][i] is subtracted from prod. The intermediate result is rounded to single-precision using the rounding mode specified in RN. The rounded result is placed into word element j of ACC[AT][i] in single-precision floating-point format.
For \([pm]\times vf32gernp\), the single-precision floating-point value in word element \(j\) of ACC[AT][i] is subtracted from prod. The intermediate result is rounded to single-precision using the rounding mode specified in RN. The rounded result is negated and placed into word element \(j\) of ACC[AT][i] in single-precision floating-point format.

For \([pm]\times vf32gernn\), the single-precision floating-point value in word element \(j\) of ACC[AT][i] is added to prod. The intermediate result is rounded to single-precision using the rounding mode specified in RN. The rounded result is negated and placed into word element \(j\) of ACC[AT][i] in single-precision floating-point format.

Otherwise, the contents of word element \(j\) of ACC[AT][i] are set to 0x0000_0000.

Unlike other vector floating-point instructions, ACC[AT] is always updated by the execution of the instruction, even when a trap-enabled exception occurs. For every multiply-add operation that is performed as part of the execution of this instruction, if an exception occurs as the result of that particular multiply-add operation, the trap-disabled exception result is returned, even if that exception type is trap-enabled. Exception detection is based on the trap-disabled definition. Exception status is and the appropriate exception status bits in the FPSCR are updated at the completion of execution of the instruction. Otherwise, behavior is the same as any vector floating-point instruction that can cause an accumulated exception. Taking a Program interrupt on a trap-enabled exception when interrupts are enabled by MSR.FE0 and MSR.FE1 is still supported, albeit with the ACC[AT] updated based on a trap-disabled result.

Let XAp be the value of 32×AX + Ap. If XAp is odd, or is in the range 4×AT to 4×AT+3, the instruction form is invalid.
Let XB be the value of 32×BX + B. If XB is in the range 4×AT to 4×AT+3, the instruction form is invalid.

Let the contents of ACC[AT] be a 4×2 matrix of double-precision floating-point values.
Let vsrcX be the concatenation of the contents of VSR[XAp] and VSR[XAp+1].
Let vsrCY be the contents of VSR[XB].

For xvf64ger, xvf64gerpp, xvf64gerpn, xvf64gernp, and xvf64gernn, let XMSK=0b1111 and YMSK=0b11.

For each integer value i from 0 to 3, and each integer value j from 0 to 1, do the following.

If bit i of XMSK is equal to 1 and bit j of YMSK is equal to 1, do the following.

Let prod be the product of the double-precision floating-point value in doubleword element i of vsrcX and the double-precision floating-point value in doubleword element j of vsrCY, having unbounded range and precision.

For [pm]xvf64ger, prod is rounded to double-precision using the rounding mode specified in RN. The rounded result is placed into doubleword element j of ACC[AT][i] in double-precision floating-point format.
For \([pm]xvf64gerpp\), \(prod\) is added to the double-precision floating-point value in doubleword element \(j\) of \(ACC[AT][i]\). The intermediate result is rounded to double-precision using the rounding mode specified in \(RN\). The rounded result is placed into doubleword element \(j\) of \(ACC[AT][i]\) in double-precision floating-point format.

For \([pm]xvf64ger\), \(prod\) is added to the negation of the double-precision floating-point value in doubleword element \(j\) of \(ACC[AT][i]\). The intermediate result is rounded to double-precision using the rounding mode specified in \(RN\). The rounded result is placed into doubleword element \(j\) of \(ACC[AT][i]\) in double-precision floating-point format.

For \([pm]xvf64gernn\), \(prod\) is added to the double-precision floating-point value in doubleword element \(j\) of \(ACC[AT][i]\). The intermediate result is rounded to double-precision using the rounding mode specified in \(RN\). The rounded result is negated and placed into doubleword element \(j\) of \(ACC[AT][i]\) in double-precision floating-point format.

For \([pm]xvf64gernp\), \(prod\) is added to the negation of the double-precision floating-point value in doubleword element \(j\) of \(ACC[AT][i]\). The intermediate result is rounded to double-precision using the rounding mode specified in \(RN\). The rounded result is negated and placed into doubleword element \(j\) of \(ACC[AT][i]\) in double-precision floating-point format.

Otherwise, the contents of doubleword element \(j\) of \(ACC[AT][i]\) are set to 0x0000_0000_0000_0000.

Unlike other vector floating-point instructions, \(ACC[AT]\) is always updated by the execution of the instruction, even when a trap-enabled exception occurs. For every multiply-add operation that is performed as part of the execution of this instruction, if an exception occurs as the result of that particular multiply-add operation, the trap-disabled exception result is returned, even if that exception type is trap-enabled. Exception detection is based on the trap-disable definition. Exception status is accumulated and the appropriate exception status bits in the FPSCR are updated at the completion of execution of the instruction. Otherwise, behavior is the same as any vector floating-point instruction that can cause an exception. Taking a Program interrupt on a trap-enabled exception when interrupts are enabled by MSR.FE0 and MSR.FE1 is still supported, albeit with the \(ACC[AT]\) updated based on a trap-disabled result.

Let $X_A$ be the value of $32 \times X_A + A$. If $X_A$ is in the range $4 \times X_A$ to $4 \times X_A + 3$, the instruction form is invalid. Let $X_B$ be the value of $32 \times X_B + B$. If $X_B$ is in the range $4 \times X_B$ to $4 \times X_B + 3$, the instruction form is invalid.

Let the contents of $ACC[AT][i].word[j]$ be a $4 \times 4$ matrix of 32-bit signed integer values.

For `xvi4ger8` or `xvi4ger8pp`, let $PMSK=0b11111111$, $XMSK=0b1111$, and $YMSK=0b1111$.

For each integer value $i$ from 0 to 3, and each integer value $j$ from 0 to 3, do the following.

If bit $i$ of $XMSK$ is equal to 1 and bit $j$ of $YMSK$ is equal to 1, do the following.

If bit 0 of $PMSK$ is equal to 1, let prod0 be the product of the 4-bit signed integer value in nibble 0 of word element $i$ of $VSR[X_A] (K[i][0])$ and the 4-bit signed integer value in byte 0 of word element $j$ of $VSR[X_B] (Y[j][0])$, sign-extended to 32 bits. Otherwise, let prod0 be the value 0.

If bit 1 of $PMSK$ is equal to 1, let prod1 be the product of the 4-bit signed integer value in nibble 1 of word element $i$ of $VSR[X_A] (K[i][1])$ and the 4-bit signed integer value in nibble 1 of word element $j$ of $VSR[X_B] (Y[j][1])$, sign-extended to 32 bits. Otherwise, let prod1 be the value 0.

If bit 2 of $PMSK$ is equal to 1, let prod2 be the product of the 4-bit signed integer value in nibble 2 of word element $i$ of $VSR[X_A] (K[i][2])$ and the 4-bit signed integer value in nibble 2 of word element $j$ of $VSR[X_B] (Y[j][2])$, sign-extended to 32 bits. Otherwise, let prod2 be the value 0.

If bit 3 of $PMSK$ is equal to 1, let prod3 be the product of the 4-bit signed integer value in nibble 3 of word element $i$ of $VSR[X_A] (K[i][3])$ and the 4-bit signed integer value in nibble 3 of word element $j$ of $VSR[X_B] (Y[j][3])$, sign-extended to 32 bits. Otherwise, let prod3 be the value 0.

If bit 4 of $PMSK$ is equal to 1, let prod4 be the product of the 4-bit signed integer value in nibble 4 of word element $i$ of $VSR[X_A] (K[i][4])$ and the 4-bit signed integer value in nibble 4 of word element $j$ of $VSR[X_B] (Y[j][4])$, sign-extended to 32 bits. Otherwise, let prod4 be the value 0.

If bit 5 of $PMSK$ is equal to 1, let prod5 be the product of the 4-bit signed integer value in nibble 5 of word element $i$ of $VSR[X_A] (K[i][5])$ and the 4-bit signed integer value in nibble 5 of word element $j$ of $VSR[X_B] (Y[j][5])$, sign-extended to 32 bits. Otherwise, let prod5 be the value 0.

If bit 6 of $PMSK$ is equal to 1, let prod6 be the product of the 4-bit signed integer value in nibble 6 of word element $i$ of $VSR[X_A] (K[i][6])$ and the 4-bit signed integer value in nibble 6 of word element $j$ of $VSR[X_B] (Y[j][6])$, sign-extended to 32 bits. Otherwise, let prod6 be the value 0.

If bit 7 of $PMSK$ is equal to 1, let prod7 be the product of the 4-bit signed integer value in nibble 7 of word element $i$ of $VSR[X_A] (K[i][7])$ and the 4-bit signed integer value in nibble 7 of word element $j$ of $VSR[X_B] (Y[j][7])$, sign-extended to 32 bits. Otherwise, let prod7 be the value 0.

Let $psum$ be the sum of prod0, prod1, prod2, prod3, prod4, prod5, prod6, and prod7.

For `[pm]xvi4ger8`, $psum$ is placed into word element $j$ of $ACC[AT][i]$ in 32-bit signed integer format.

For `[pm]xvi4ger8ppp`, $psum$ is added to the 32-bit signed integer value in word element $j$ of $ACC[AT][i]$, and the result is placed into word element $j$ of $ACC[AT][i]$ in 32-bit signed integer format.

Otherwise, let $ACC[AT][i][j]$ is set to $0x0000_0000$.

</tbody>
</table>

1. Floating-point multiplication is based on exponent addition and multiplication of the significands.
2. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
3. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

Let \( XT \) be the value \( 32 \times TX + T \).
Let \( XA \) be the value \( 32 \times AX + A \).
Let \( XB \) be the value \( 32 \times BX + B \).

For each integer value \( i \) from 0 to 1, do the following.

For \( \text{xvmaddadp} \), do the following.
- Let \( src1 \) be the double-precision floating-point operand in doubleword element \( i \) of \( VSR[XA] \).
- Let \( src2 \) be the double-precision floating-point operand in doubleword element \( i \) of \( VSR[XT] \).
- Let \( src3 \) be the double-precision floating-point operand in doubleword element \( i \) of \( VSR[XB] \).

For \( \text{xvmaddmdp} \), do the following.
- Let \( src1 \) be the double-precision floating-point operand in doubleword element \( i \) of \( VSR[XA] \).
- Let \( src2 \) be the double-precision floating-point operand in doubleword element \( i \) of \( VSR[XB] \).
- Let \( src3 \) be the double-precision floating-point operand in doubleword element \( i \) of \( VSR[XT] \).

\( src1 \) is multiplied\(^1\) by \( src3 \), producing a product having unbounded range and precision.

See part 1 of Table 126.

\( src2 \) is added\(^2\) to the product, producing a sum having unbounded range and precision.

The sum is normalized\(^3\).

See part 2 of Table 126.

The intermediate result is rounded to double-precision using the rounding mode specified by \( RN \).

The result is placed into doubleword element \( i \) of \( VSR[XT] \) in double-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 823.

If a trap-enabled exception occurs in any element of the vector, no results are written to \( VSR[XT] \).

#### Explanation:

| `src1` | The double-precision floating-point value in doubleword element `i` of `VSR[IA]` (where `i = 0, 1`).
| `src2` | For `xvmadaddp`, the double-precision floating-point value in doubleword element `i` of `VSR[XT]` (where `i = 0, 1`).
| `src3` | For `xvmadaddp`, the double-precision floating-point value in doubleword element `i` of `VSR[XB]` (where `i = 0, 1`).
| dQNaN | Default quiet NaN (`0x7FF8_0000_0000_0000`).
| NZF | Nonzero finite number.
| Rez | Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs). Can also occur with nonzero finite number source operands.
| Q(x) | Return a QNaN with the payload of `x`.
| A(x, y) | Return the normalized sum of floating-point value `x` and floating-point value `y`, having unbounded range and precision.
| Note: If `x = -y`, `x` is considered to be an exact-zero-difference result (Rez).
| M(x, y) | Return the normalized product of floating-point value `x` and floating-point value `y`, having unbounded range and precision.
| p | The intermediate product having unbounded range and precision.
| v | The intermediate result having unbounded range and precision.
VSX Vector Multiply-Add Type-A
Single-Precision XX3-form

\[ \text{xvmaddasp} \ XT, XA, XB \]

\[ \begin{array}{cccccc}

### Explanation:

- **src1**: The single-precision floating-point value in word element \(i\) of VSR[ XB] (where \(i = \{0, 1, 2, 3\}\).

- **src2**: For xvmaddasp, the single-precision floating-point value in word element \(i\) of VSR[ XT] (where \(i = \{0, 1, 2, 3\}\). For xvmaddmsp, the single-precision floating-point value in word element \(i\) of VSR[ X] (where \(i = \{0, 1, 2, 3\}\).

- **src3**: For xvmaddasp, the single-precision floating-point value in word element \(i\) of VSR[ XB] (where \(i = \{0, 1, 2, 3\}\). For xvmaddmsp, the single-precision floating-point value in word element \(i\) of VSR[ X] (where \(i = \{0, 1, 2, 3\}\).

- **dQNaN**: Default quiet NaN (0x7FC0_0000).

- **NZF**: Nonzero finite number.

- **Rezd**: Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs). Can also occur with two nonzero finite number source operands.

- **Q(x)**: Return a QNaN with the payload of \(x\).

- **A(x, y)**: Return the normalized sum of floating-point value \(x\) and floating-point value \(y\), having unbounded range and precision.

  **Note:** If \(x = -y\), \(v\) is considered to be an exact-zero-difference result (Rezd).

- **M(x, y)**: Return the normalized product of floating-point value \(x\) and floating-point value \(y\), having unbounded range and precision.

  - **p**: The intermediate product having unbounded range and precision.

  - **v**: The intermediate result having unbounded range and precision.
Let $XT$ be the value $32\times T + T$.
Let $XA$ be the value $32\times AX + A$.
Let $XB$ be the value $32\times BX + B$.

For each integer value $i$ from 0 to 1, do the following.
Let $src1$ be the double-precision floating-point operand in doubleword element $i$ of $VSR[AX]$.

Let $src2$ be the double-precision floating-point operand in doubleword element $i$ of $VSR[XB]$.

If $src1$ is greater than $src2$, $src1$ is placed into doubleword element $i$ of $VSR[XT]$ in double-precision format. Otherwise, $src2$ is placed into doubleword element $i$ of $VSR[XT]$ in double-precision format.

The maximum of $+0$ and $-0$ is $+0$. The maximum of a QNaN and any value is that value. The maximum of any value and an SNaN when $VE=0$ is that SNaN converted to a QNaN.

See Table 128.

If a trap-enabled exception occurs in any element of the vector, no results are written to $VSR[XT]$.

**Explanation:**
- **src1** The single-precision floating-point value in word element i of VSR[XA] (where i = {0, 1, 2, 3}).
- **src2** The single-precision floating-point value in word element i of VSR[XT] (where i = {0, 1, 2, 3}).
- **NZF** Nonzero finite number.
- **Q(x)** Return a QNaN with the payload of x.
- **M(x, y)** Return the greater of floating-point value x and floating-point value y.
- **T(x)** The value x is placed in word element i (i = {0, 1, 2, 3}) of VSR[XT] in single-precision format.
- **fx(x)** If FPSCR.x is equal to 0, FPSCR.FX is set to 1. FPSCR.x is set to 1.

**Table 129. Actions for xvmaxsp**
VSX Vector Minimum Double-Precision
XX3-form

```

Let XT be the value 32×TX + T.
Let XA be the value 32×AX + A.
Let XB be the value 32×BX + B.

For each integer value i from 0 to 1, do the following.
Let src1 be the double-precision floating-point operand in doubleword element i of VSR[XA].

Let src2 be the double-precision floating-point operand in doubleword element i of VSR[XB].

If src1 is less than src2, src1 is placed into doubleword element i of VSR[XT] in double-precision format. Otherwise, src2 is placed into doubleword element i of VSR[XT] in double-precision format.

The minimum of +0 and -0 is -0. The minimum of a QNaN and any value is that value. The minimum of any value and an SNaN when VE=0 is that SNaN converted to a QNaN.

See Table 130.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

end

if ex_flag=0 then VSR[32×TX+T] ← result

Let XT be the value 32×TX + T. Let XA be the value 32×AX + A. Let XB be the value 32×BX + B.

For each integer value i from 0 to 1, do the following.

For xvmsubadp, do the following.
- Let src1 be the double-precision floating-point operand in doubleword element i of VSR[XA].
- Let src2 be the double-precision floating-point operand in doubleword element i of VSR[XT].
- Let src3 be the double-precision floating-point operand in doubleword element i of VSR[XB].

src1 is multiplied[1] by src3, producing a product having unbounded range and precision.

See part 1 of Table 132.

src2 is negated and added[2] to the product, producing a sum having unbounded range and precision.

The sum is normalized[3].

See part 2 of Table 132.

The intermediate result is rounded to double-precision using the rounding mode specified by RN.

The result is placed into doubleword element i of VSR[XT] in double-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 823.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

Special Registers Altered
FX OX UX XX VXSNAN VXISI VXIMZ

---

1. Floating-point multiplication is based on exponent addition and multiplication of the significands.
2. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
3. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

### Explanation:

| `src1` | The double-precision floating-point value in doubleword element `i` of `VSR[AA]` (where `i` ∈ {0, 1}). |
| `src2` | For `xvmsubadp`, the double-precision floating-point value in doubleword element `i` of `VSR[XT]` (where `i` ∈ {0, 1}). |
| `src3` | For `xvmsubadp`, the double-precision floating-point value in doubleword element `i` of `VSR[XB]` (where `i` ∈ {0, 1}). |
| `dQNaN` | Default quiet NaN (`0x7FF8_0000_0000_0000`). |
| `NZF` | Nonzero finite number. |
| `Rezd` | Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs). Can also occur with two nonzero finite number source operands. |
| `Q(x)` | Return a QNaN with the payload of `x`. |
| `S(x,y)` | Return the normalized sum of floating-point value `x` and negated floating-point value `y`, having unbounded range and precision. Note: If `x = y`, `v` is considered to be an exact-zero-difference result (`Rezd`). |
| `M(x,y)` | Return the normalized product of floating-point value `x` and floating-point value `y`, having unbounded range and precision. |
| `p` | The intermediate product having unbounded range and precision. |
| `v` | The intermediate result having unbounded range and precision. |

FX \text{OX \& UX \& VXSNAN \& VXISI \& VXI MW}

---

1. Floating-point multiplication is based on exponent addition and multiplication of the significands.
2. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent incremented by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
3. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

#### Explanation:

- **src1**: The single-precision floating-point value in word element \(i\) of \(VSR[XA]\) (where \(i = \{0, 1, 2, 3\}\).
- **src2**: For \(xvmsubsp\), the single-precision floating-point value in word element \(i\) of \(VSR[XT]\) (where \(i = \{0, 1, 2, 3\}\)).
- **src3**: For \(xvmsubsp\), the single-precision floating-point value in word element \(i\) of \(VSR[XA]\) (where \(i = \{0, 1, 2, 3\}\)).
- **dQNaN**: Default quiet NaN (\(\times[7F]0000\)).
- **NZF**: Nonzero finite number.
- **Rezd**: Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs). Can also occur with two nonzero finite number source operands.
- **Q(x)**: Return a QNaN with the payload of \(x\).
- **S(x, y)**: Return the normalized sum of floating-point value \(x\) and negated floating-point value \(y\), having unbounded range and precision. Note: If \(x = y\), \(x\) is considered to be an exact-zero-difference result (\(\times[00]\)).
- **M(x, y)**: Return the normalized product of floating-point value \(x\) and floating-point value \(y\), having unbounded range and precision.
- **v**: The intermediate product having unbounded range and precision.
- **p**: The intermediate result having unbounded range and precision.

Let XT be the value \(32\times TX + T\).
Let XA be the value \(32\times XA + A\).
Let XB be the value \(32\times XB + B\).

For each integer value \(i\) from 0 to 1, do the following.

Let src1 be the double-precision floating-point operand in doubleword element \(i\) of VSR[XA].

Let src2 be the double-precision floating-point operand in doubleword element \(i\) of VSR[XB].

src1 is multiplied\(^1\) by src2, producing a product having unbounded range and precision.

The product is normalized\(^2\).

See Table 134.

The intermediate result is rounded to double-precision using the rounding mode specified by RN.

The result is placed into doubleword element \(i\) of VSR[XT] in double-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 823.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

For \texttt{xvmnaddmdp}, do the following.
– Let src1 be the double-precision floating-point operand in doubleword element i of VSR[XA].
– Let src2 be the double-precision floating-point operand in doubleword element i of VSR[XB].
– Let src3 be the double-precision floating-point operand in doubleword element i of VSR[XT].

src1 is multiplied\(^1\) by src3, producing a product having unbounded range and precision.

See part 1 of Table 136.

src2 is added\(^2\) to the product, producing a sum having unbounded range and precision.

The sum is normalized\(^3\).

See part 2 of Table 136.

The intermediate result is rounded to double-precision using the rounding mode specified by RN.

The result is negated and placed into doubleword element i of VSR[XT] in double-precision format.

See Table 137, “Vector Floating-Point Final Result with Negation,” on page 926.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

Special Registers Altered
FX OX UX XX VXSNAN VXISI VXIMZ

1. Floating-point multiplication is based on exponent addition and multiplication of the significands.
2. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
3. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

**Explanation:**

- **src1:** The double-precision floating-point value in doubleword element \( i \) of VSR[xt] (where \( i = [0,1] \)).
- **src2:** For \texttt{xvmadddp}, the double-precision floating-point value in doubleword element \( i \) of VSR[xt] (where \( i = [0,1] \)).
- **src3:** For \texttt{xvmadddp}, the double-precision floating-point value in doubleword element \( i \) of VSR[xt] (where \( i = [0,1] \)).
- **dQNaN:** Default quiet NaN (\( 0x7FF0_0000_0000_0000 \)).
- **NZF:** Nonzero finite number.
- **Rezd:** Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs). Can also occur with two nonzero finite number source operands.
- **Q(x):** Return a QNaN with the payload of \( x \).
- **M(x, y):** Return the normalized sum of floating-point value \( x \) and floating-point value \( y \), having unbounded range and precision.
- **p:** The intermediate product having unbounded range and precision.
- **v:** The intermediate result having unbounded range and precision.

### Explanation:

- The results do not depend on this condition.
- error() The system error handler is invoked for the trap-enabled exception if MSR.FE0 and MSR.FE1 are set to any mode other than the ignore-exception mode. Update of the target VSR is suppressed for all vector elements.
- fx(x) FPSCR.x is set to 1 if FPSCR.x=0.
- q The value defined in Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 661, significand rounded to the target precision, unbounded exponent range.
- r The value defined in Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 661, significand rounded to the target precision, bounded exponent range.
- v The precise intermediate result defined in the instruction having unbounded significand precision, unbounded exponent range.
- N(x) The value x is negated by complementing the sign bit of x.
- T(x) The value x is placed in element i of VSR[XT] in the target precision format (where i=x[0,1] for results with 64-bit elements, and i=x[0,1,3,4] for results with 32-bit elements).

Let XT be the value 32×TX + T.
Let XA be the value 32×AX + A.
Let XB be the value 32×BX + B.

For each integer value i from 0 to 3, do the following.

For `xvmaddasp`, do the following.
  - Let src1 be the single-precision floating-point operand in word element i of VSR[AX].
  - Let src2 be the single-precision floating-point operand in word element i of VSR[XT].
  - Let src3 be the single-precision floating-point operand in word element i of VSR[XB].

For `xvmaddmsp`, do the following.
  - Let src1 be the single-precision floating-point operand in word element i of VSR[AX].
  - Let src2 be the single-precision floating-point operand in word element i of VSR[XB].
  - Let src3 be the single-precision floating-point operand in word element i of VSR[XT].

src1 is multiplied[1] by src3, producing a product having unbounded range and precision.

See part 1 of Table 138.

src2 is added[2] to the product, producing a sum having unbounded range and precision.

The sum is normalized[3].

See part 2 of Table 138.

The intermediate result is rounded to single-precision using the rounding mode specified by RN.

The result is negated and placed into word element i of VSR[XT] in single-precision format.

See Table 137, “Vector Floating-Point Final Result with Negation,” on page 926.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

### Explanation:

- **src1**: The single-precision floating-point value in word element i of VSR[XA] (where i=0,1,2,3).
- **src2**: For **xvmmaddsp**, the single-precision floating-point value in word element i of VSR[XT] (where i=0,1,2,3).
- **src3**: For **xvmmaddsp**, the single-precision floating-point value in word element i of VSR[XB] (where i=0,1,2,3).
- **dQNan**: Default quiet NaN (0x3F00_0000).
- **NZF**: Nonzero finite number.
- **Rezd**: Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs). Can also occur with two nonzero finite number operands.
- **Q(x)**: Return a QNaN with the payload of x.
- **A(x,y)**: Return the normalized sum of floating-point value x and floating-point value y, having unbounded range and precision.
- **M(x,y)**: Return the normalized product of floating-point value x and floating-point value y, having unbounded range and precision.
- **p**: The intermediate product having unbounded range and precision.
- **v**: The intermediate result having unbounded range and precision.

#### Special Registers Altered

- FX
- UX
- VXSNAN
- VXISI
- VXIMZ

---

1. Floating-point multiplication is based on exponent addition and multiplication of the significands.
2. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
3. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

Let XT be the value $32 \times TX + T$.
Let XA be the value $32 \times AX + A$.
Let XB be the value $32 \times BX + B$.

For each integer value i from 0 to 1, do the following.

For `xvnmsubadp`, do the following.
- Let src1 be the double-precision floating-point operand in doubleword element i of VSR[XA].
- Let src2 be the double-precision floating-point operand in doubleword element i of VSR[XT].
- Let src3 be the double-precision floating-point operand in doubleword element i of VSR[XB].

For `xvnmsubmdp`, do the following.
- Let src1 be the double-precision floating-point operand in doubleword element i of VSR[XA].
- Let src2 be the double-precision floating-point operand in doubleword element i of VSR[XB].
- Let src3 be the double-precision floating-point operand in doubleword element i of VSR[XT].

src1 is multiplied[1] by src3, producing a product having unbounded range and precision.

See part 1 of Table 139.

src2 is negated and added[2] to the product, producing a sum having unbounded range and precision.

The sum is normalized[3].

See part 2 of Table 139.

The intermediate result is rounded to double-precision using the rounding mode specified by RN.

The result is negated and placed into doubleword element i of VSR[XT] in double-precision format.

See Table 137, “Vector Floating-Point Final Result with Negation,” on page 926.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

Explanations:

src1  The double-precision floating-point value in doubleword element i of VSR[XA] (where i={0,1}).
src2  For xvnmsubadp, the double-precision floating-point value in doubleword element i of VSR[XT] (where i={0,1}).
src3  For xvnmsubadp, the double-precision floating-point value in doubleword element i of VSR[XB] (where i={0,1}).
For xvnmsubdmp, the double-precision floating-point value in doubleword element i of VSR[XT] (where i={0,1}).
d\text{QNaN}  Default quiet NaN (0x7FFE_0000_0000_0000).
NZF  Nonzero finite number.
Rezd  Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs). Can also occur with two nonzero finite number source operands.
Q(x)  Return a QNaN with the payload of x.
S(x,y)  Return the normalized sum of floating-point value x and negated floating-point value y, having unbounded range and precision.
Note: If x = -y, v is considered to be an exact-zero-difference result (Rezd).
M(x,y)  Return the normalized product of floating-point value x and floating-point value y, having unbounded range and precision.
p  The intermediate product having unbounded range and precision.
v  The intermediate result having unbounded range and precision.
VSX Vector Negative Multiply-Subtract Type-A
Single-Precision XX3-form

Let XT be the value $32 \times TX + T$.
Let XA be the value $32 \times AX + A$.
Let XB be the value $32 \times BX + B$.

For each integer value $i$ from 0 to 3, do the following.

For \textit{xvnmsubasp}, do the following.
- Let src1 be the single-precision floating-point operand in word element $i$ of VSR[XA].
- Let src2 be the single-precision floating-point operand in word element $i$ of VSR[XT].
- Let src3 be the single-precision floating-point operand in word element $i$ of VSR[XB].

src1 is multiplied\(^1\) by src3, producing a product having unbounded range and precision.

See part 1 of Table 140.

ds rc2 is negated and added\(^2\) to the product, producing a sum having unbounded range and precision.

The sum is normalized\(^3\).

See part 2 of Table 140.

The intermediate result is rounded to single-precision using the rounding mode specified by RN.

The result is negated and placed into word element $i$ of VSR[XT] in single-precision format.

See Table 137, "Vector Floating-Point Final Result with Negation," on page 926.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

</tbody>
</table>

1. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.

2. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

</tbody>
</table>

**Explanation:**

- `src1` The double-precision floating-point value in doubleword element i of VSR[XA] (where i={0,1}).
- `src2` The double-precision floating-point value in doubleword element i of VSR[XB] (where i={0,1}).
- `dQNaN` Default quiet NaN (0x7FF8_0000_0000_0000).
- `NZF` Nonzero finite number.
- `Rezd` Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs).
- `S(x,y)` Return the normalized sum of floating-point value x and negated floating-point value y, having unbounded range and precision.
  - **Note:** If x = -y, v is considered to be an exact-zero-difference result (Rezd).
- `Q(x)` Return a QNaN with the payload of x.
- `v` The intermediate result having unbounded significand precision and unbounded exponent range.
VSX Vector Subtract Single-Precision
XX3-form

Let $XT$ be the value $32\times TX + T$.
Let $XA$ be the value $32\times AX + A$.
Let $XB$ be the value $32\times BX + B$.

For each integer value $i$ from 0 to 3, do the following.
Let $src1$ be the single-precision floating-point operand in word element $i$ of $VSR[XA]$.
Let $src2$ be the single-precision floating-point operand in word element $i$ of $VSR[XB]$.

$src2$ is negated and added\(^1\) to $src1$, producing a sum having unbounded range and precision.

The sum is normalized\(^2\).

See Table 144.

The intermediate result is rounded to single-precision using the rounding mode specified by $RN$.

The result is placed into word element $i$ of $VSR[XT]$ in single-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 823.

If a trap-enabled exception occurs in any element of the vector, no results are written to $VSR[XT]$.

|------|----------------|----------------|----------------|----------------|

---

1. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.

2. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

Let XT be the sum 32×TX + T.

Let XB be the sum 32×BX + B.

For each integer value i from 0 to 3, do the following.

Let src be the single-precision floating-point value in word element i of VSR[XB].

The significand of src is placed into word element i of VSR[XT] in unsigned integer format. If src is a normal value, the implicit leading bit is set to 1.

Chapter 7. Vector-Scalar Extension Facility 969
VSX Vector Generate PCV from Byte Mask
X-form

Let $XT$ be the value $32 \times TX + T$.

If $IMM=0b00000$, let $pcv$ be the permute control vector required to enable a left-indexed permute ($vperm$ or $xxperm$) to implement an expansion of the leftmost byte elements of a source vector into the byte elements of a result vector specified by the byte-element mask in $VSR[VRB+32]$.

If $IMM=0b00001$, let $pcv$ be the permute control vector required to enable a left-indexed permute ($vperm$ or $xxperm$) to implement a compression of the sparse byte elements in a source vector specified by the byte-element mask in $VSR[VRB+32]$ into the leftmost byte elements of a result vector.

If $IMM=0b00010$, let $pcv$ be the permute control vector required to enable a right-indexed permute ($vpermr$ or $xxpermr$) to implement an expansion of the rightmost byte elements of a source vector into the byte elements of a result vector specified by the byte-element mask in $VSR[VRB+32]$.

If $IMM=0b00011$, let $pcv$ be the permute control vector required to enable a right-indexed permute ($vpermr$ or $xxpermr$) to implement a compression of the sparse byte elements in a source vector specified by the byte-element mask in $VSR[VRB+32]$ into the rightmost byte elements of a result vector.

$pcv$ is placed into $VSR[XT]$.

Unused values of $IMM$ are reserved.

Special Registers Altered:
None
Programming Note

The following is an example of how a Load VSX Vector and Expand Byte, when using Big-Endian byte-ordering, can be emulated using VSX Vector Generate PCV from Mask Byte.

```
xgenpcvbm vPCV, vMASK, 0b00000    // generates the required permute control vector for Big-Endian expansion
vcntmbb vN, vMASK, 0b1           // calculates N, number of true byte-mask elements
lxvl vLD, EA, rN                  // loads N bytes
// Option 1: expand & merge
xxperm vT, vLD, vT, vPCV          // perform the expansion,
// specifying vT as 2nd source operand causes expanded load data to be
// merged into VSR[vT]
// Option 2: expand & zero
xxperm vT, vLD, vZERO, vPCV       // perform the expansion,
// specifying vZERO (vector of 0s) as 2nd source operand causes expanded
// load data to be placed into VSR[vT] with other elements set to 0
```

The following is an example of how a Load VSX Vector Expand Byte, when using Little-Endian byte-ordering, can be emulated using VSX Vector Generate PCV from Mask Byte.

```
xgenpcvbm vPCV, vMASK, 0b00010    // generates the required permute control vector for Big-Endian expansion
vcntmbb vN, vMASK, 0b1           // calculates N, number of true byte-mask elements
lxvl vLD, EA, rN                  // loads N bytes
// Option 1: expand & merge
xxperm vT, vLD, vT, vPCV          // perform the expansion,
// specifying vT as 2nd source operand causes expanded load data to be
// merged into VSR[vT]
// Option 2: expand & zero
xxperm vT, vLD, vZERO, vPCV       // perform the expansion,
// specifying vZERO (vector of 0s) as 2nd source operand causes expanded
// load data to be placed into VSR[vT] with other elements set to 0
```

The following is an example of how a VSX Vector Compress Byte and Store, when using Big-Endian byte-ordering, can be emulated using VSX Vector Generate PCV from Mask Byte.

```
xgenpcvbm vPCV, vMASK, 0b00001    // generates the required permute control vector for Big-Endian compression
vcntmbb vN, vMASK, 0b1           // calculates N, number of true byte-mask elements
xxperm vSD, vS, vS, vPCV          // perform the compression
stxvl vSD, rEA, rN                // store N bytes
```

The following is an example of how a VSX Vector Byte Compress and Store, when using Little-Endian byte-ordering, can be emulated using VSX Vector Generate PCV from Mask.

```
xgenpcvbm vPCV, vMASK, 0b00011    // generates the required permute control vector for Big-Endian compression
vcntmbb vN, vMASK, 0b1           // calculates N, number of true byte-mask elements
xxperm vSD, vS, vS, vPCV          // perform the compression
stxvl vSD, rEA, rN                // store N bytes
```

Let XT be the value \(32 \times TX + T\).

If \(\text{IMM}=0b00000\), let \text{pcv} be the permute control vector required to enable a left-indexed permute (\text{vperm} or \text{xxperm}) to implement an expansion of the leftmost halfword elements of a source vector into the halfword elements of a result vector specified by the halfword-element mask in \text{VSR[VRB+32]}. If \(\text{IMM}=0b00001\), let \text{pcv} be the permute control vector required to enable a left-indexed permute (\text{vperm} or \text{xxperm}) to implement a compression of the sparse halfword elements in a source vector specified by the halfword-element mask in \text{VSR[VRB+32]} into the leftmost halfword elements of a result vector.

If \(\text{IMM}=0b00010\), let \text{pcv} be the permute control vector required to enable a right-indexed permute (\text{vpermr} or \text{xxpermr}) to implement an expansion of the rightmost halfword elements of a source vector into the halfword elements of a result vector specified by the halfword-element mask in \text{VSR[VRB+32]}. If \(\text{IMM}=0b00011\), let \text{pcv} be the permute control vector required to enable a right-indexed permute (\text{vpermr} or \text{xxpermr}) to implement a compression of the sparse halfword elements in a source vector specified by the halfword-element mask in \text{VSR[VRB+32]} into the rightmost halfword elements of a result vector.

\text{pcv} is placed into \text{VSR[XT]}.

Unused values of \text{IMM} are reserved.

**Special Registers Altered:** None
Chapter 7. Vector-Scalar Extension Facility

The following is an example of how a Load VSX Vector Expand Word, when using Big-Endian byte-ordering, can be emulated using VSX Vector Generate PCV from Mask Word.

```assembly
xxgenpcvwm vPCV, vMASK, 0b000000 // generates the required permute control vector for Big-Endian expansion
cntmbw rN, vMASK, 0b01 // calculates N, number of true word-mask elements, adjusted to # of bytes
lxvl vLD, EA, rN // loads 4xN bytes

// Option 1: expand & merge
xxperm vT, vLD, vT, vPCV // perform the expansion,
// specifying vT as 2nd source operand causes expanded load data to be
// merged into VSR[vT]

// Option 2: expand & zero
xxperm vT, vLD, vZERO, vPCV // perform the expansion,
// specifying vZERO (vector of 0s) as 2nd source operand causes expanded
// load data to be placed into VSR[vT] with other elements set to 0
```

The following is an example of how a Load VSX Vector Expand Word, when using Little-Endian byte-ordering, can be emulated using VSX Vector Generate PCV from Mask Word.

```assembly
xxgenpcvwm vPCV, vMASK, 0b00010 // generates the required permute control vector for Little-Endian expansion
cntmbw rN, vMASK, 0b01 // calculates N, number of true word-mask elements, adjusted to # of bytes
lxvl vLD, EA, rN // loads 4xN bytes

// Option 1: expand & merge
xxperm vT, vLD, vT, vPCV // perform the expansion,
// specifying vT as 2nd source operand causes expanded load data to be
// merged into VSR[vT]

// Option 2: expand & zero
xxperm vT, vLD, vZERO, vPCV // perform the expansion,
// specifying vZERO (vector of 0s) as 2nd source operand causes expanded
// load data to be placed into VSR[vT] with other elements set to 0
```

The following is an example of how a Store VSX Vector Compress Word, when using Big-Endian byte-ordering, can be emulated using VSX Vector Generate PCV from Mask Word.

```assembly
xxgenpcvwm vPCV, vMASK, 0b00001 // generates the required permute control vector for Big-Endian compression
cntmbw rN, vMASK, 0b01 // calculates N, number of true word-mask elements, adjusted to # of bytes
xxperm vSD, vS, vS, vPCV // perform the compression
stxvl vSD, rEA, rN // store 4xN bytes
```

The following is an example of how a Store VSX Vector Compress Word, when using Little-Endian byte-ordering, can be emulated using VSX Vector Generate PCV from Mask Word.

```assembly
xxgenpcvwm vPCV, vMASK, 0b00011 // generates the required permute control vector for Little-Endian compression
cntmbw rN, vMASK, 0b01 // calculates N, number of true word-mask elements, adjusted to # of bytes
xxperm vSD, vS, vS, vPCV // perform the compression
stxvl vSD, rEA, rN // store 4xN bytes
```

---

**Programming Note**

During extended periods of the execution of an application when there isn't any active use of the Accumulators and VSX Vector GER instructions, hardware may deactivate these facilities for power savings. Once deactivated, while any attempted execution of any \( xmfacc, xxmtacc, xxsetaccz \), or VSX Vector GER instruction will cause these facilities to become reactivated, this reactivation causes significant delay beyond the normal execution of these instructions. This delay can be avoided by periodically issuing an \( xxmfacc \) with \( AS=0 \) instruction during extended times that the facilities are not being used to keep the facilities activated. Since the contents of \( ACC[0] \) will be undefined after the first execution, performance on subsequent executions of \( xxmfacc 0 \) can be expected to be degraded compared to performance when the contents of \( ACC[0] \) are defined. As such, to keep the facilities activated, \( xxmfacc 0 \) should be used with attention to performance implications.

    VSR[32×TX+T].byte[i] ← src.byte[eidx]
  else
    VSR[32×TX+T].byte[i] ← 0x00
  end

Let XT be the value 32×TX + T.
Let XA be the value 32×AX + A.
Let XB be the value 32×BX + B.
Let XC be the value 32×CX + C.

Let UIM specify which 32-byte section of the long vector that src contains.

Let src be the concatenation VSR[XA] and VSR[XB], comprising a 32-byte section of up to a 128-byte vector.

For each integer value i from 0 to 15, do the following.

  Let eidx be the contents of bits 3:7 of byte element i of VSR[XC].
  jr

  if UIM is equal to the contents of bits 0:2 of byte element i of VSR[XC], the contents of byte element eidx of src are placed into byte element i of VSR[XT]. Otherwise, the contents of byte element i of VSR[XT] are set to 0.

VSR Data Layout for xxpermX

Programming Note

The following is an example of emulating 256-bit xxperm, where a 256-bit vector is contained in a pair of VSRs. The instruction is capable of emulating up to a 1024-bit xxperm.

vTA = xxperm(vA0, vA1, vC0, 0);
vTB = xxperm(vB0, vB1, vC0, 1);
vTC0 = xxperm(vA0, vA1, vC1, 0);
vTC1 = xxperm(vB0, vB1, vC1, 1);

vT0 = xxlor(vTA0, vTB);
vT1 = xxlor(vTC0, vTC1);

Programming Note

The following is an example of a parallel table lookup. In this case, a 16-way SIMD 256-entry byte table lookup.

vT0 = xxperm(vS0, vS1, vINDEX, 0);
vT1 = xxperm(vS2, vS3, vINDEX, 1);
vT2 = xxperm(vS4, vS5, vINDEX, 2);
vT3 = xxperm(vS6, vS7, vINDEX, 3);
vT4 = xxperm(vS8, vS9, vINDEX, 4);
vT5 = xxperm(vSA, vSB, vINDEX, 5);
vT6 = xxperm(vSC, vSD, vINDEX, 6);
vT7 = xxperm(vSE, vSF, vINDEX, 7);

vT0 = xxlor(vT0, vT1);
vT1 = xxlor(vT2, vT3);
vT2 = xxlor(vT4, vT5);
vT3 = xxlor(vT6, vT7);

vT0 = xxlor(vT0, vT1);
vT1 = xxlor(vT2, vT3);

Appendix B. Densely Packed Decimal

The trailing significand field of the decimal floating-point data format is encoded using Densely Packed Decimal (DPD). DPD encoding is a compression technique which supports the representation of decimal integers of arbitrary length. Translation operates on three Binary Coded Decimal (BCD) digits at a time compressing the 12 bits into 10 bits with an algorithm that can be applied or reversed using simple Boolean operations. In the following examples, a 3-digit BCD number is represented as (abcd)(efgh)(ijkm), a 10-bit DPD number is represented as (pqr)(stu)(v)(wxy), and the Boolean operations, & (AND), | (OR), and ¬ (NOT) are used.

B.1 BCD-to-DPD Translation

The translation from a 3-digit BCD number to a 10-bit DPD can be performed through the following Boolean operations.

\[
\begin{align*}
p &= (f \& a \& i \& \neg e) \mid (j \& a \& \neg i) \mid (b \& \neg a) \\
qu &= (g \& a \& i \& \neg e) \mid (k \& a \& \neg i) \mid (c \& \neg a) \\
q &= d \\
s &= (j \& \neg a \& e \& \neg i) \mid (f \& \neg i \& \neg e) \\
t &= (k \& \neg a \& e \& \neg i) \mid (g \& \neg i \& \neg e) \\
u &= (j \& \neg a \& e \& \neg i) \mid (f \& \neg i \& \neg e) \\
v &= (j \& \neg a \& e \& \neg i) \mid (f \& \neg i \& \neg e) \\
w &= (j \& \neg a \& e \& \neg i) \mid (f \& \neg i \& \neg e) \\
x &= (j \& \neg a \& e \& \neg i) \mid (f \& \neg i \& \neg e) \\
y &= (j \& \neg a \& e \& \neg i)
\end{align*}
\]

Alternatively, the following table can be used to perform the translation. The most significant bit of the three BCD digits (left column) is used to select a specific 10-bit encoding (right column) of the DPD.

<table>
<thead>
<tr>
<th>ae</th>
<th>pqr</th>
<th>stu</th>
<th>v</th>
<th>wxy</th>
</tr>
</thead>
<tbody>
<tr>
<td>000</td>
<td>bcd</td>

</tr>
</tbody>
</table>

The full translation of a 3-digit BCD number (000 - 999) to a 10-bit DPD is shown in Table 146 on page 1009, with the DPD entries shown in hexadecimal format. The BCD number is produced by replacing ‘_’ in the leftmost column with the corresponding digit along the top row. The table is split into two halves, with the right half being a continuation of the left half.

B.2 DPD-to-BCD Translation

The translation from a 10-bit DPD to a 3-digit BCD number can be performed through the following Boolean operations.

\[
\begin{align*}
a &= (\neg s \& v \& w) \mid (t \& v \& w \& s) \mid (v \& w \& \neg x) \\
b &= (p \& s \& x \& \neg t) \mid (p \& \neg w) \mid (p \& \neg v) \\
c &= (q \& s \& x \& \neg t) \mid (q \& \neg w) \mid (q \& \neg v) \\
d &= r \\
e &= (v \& \neg w \& x) \mid (s \& v \& w \& x) \\
f &= (p \& t \& v \& w \& x \& \neg s) \mid (s \& \neg x \& v) \mid (s \& \neg v) \\
g &= (q \& t \& w \& v \& x \& \neg s) \mid (t \& \neg x \& v) \mid (t \& \neg v) \\
h &= u \\
i &= (t \& v \& w \& x) \mid (s \& v \& w \& x) \\
j &= (p \& s \& \neg t \& w \& v) \mid (s \& v \& \neg w \& x) \\
k &= (q \& s \& \neg t \& v \& w) \mid (t \& v \& \neg w \& x) \\
m &= y
\end{align*}
\]

Alternatively, the following table can be used to perform the translation. A combination of five bits in the DPD encoding (leftmost column) are used to specify a translation to the 3-digit BCD encoding. Dashes (-) in the table are don’t cares, and can be either one or zero.
The full translation of the 10-bit DPD to a 3-digit BCD number is shown in Table 147 on page 1010. The 10-bit DPD index is produced by concatenating the 6-bit value shown in the left column with the 4-bit index along the top row, both represented in hexadecimal. The values in parentheses are non-preferred translations and are explained further in the following section.

### B.3 Preferred DPD encoding

Translating from a 3-digit BCD number (1000 numbers) to a 10-bit DPD encoding (1024 combinations) leaves 24 redundant translations. The 24 redundant combinations are evenly assigned to eight BCD numbers and are shown in the following table, with the non-preferred encoding in parentheses. The preferred encoding is produced by translating a 3-digit BCD number with the translation table or Boolean operations shown in Section B.1. The redundant DPD encodings are all valid and will be correctly translated to their respective BCD value through the mechanisms provided in Section B.2. For decimal floating-point operations all DPD encodings are recognized as source operands.

Table 147: DPD-to-BCD translation
Appendix C. Assembler Extended Mnemonics

In order to make assembler language programs simpler to write and easier to understand, a set of extended mnemonics and symbols is provided that defines simple shorthand for the most frequently used forms of Branch Conditional, Compare, Trap, Rotate and Shift, and certain other instructions.

Assemblers should provide the extended mnemonics and symbols listed here, and may provide others.

C.1 Symbols

The following symbols are defined for use in instructions (basic or extended mnemonics) that specify a Condition Register field or a Condition Register bit. The first five (lt, ..., un) identify a bit number within a CR field. The remainder (cr0, ..., cr7) identify a CR field. An expression in which a CR field symbol is multiplied by 4 and then added to a bit-number-within-CR-field symbol and 32 can be used to identify a CR bit.

<td>7</td>
<td>CR Field 7</td>
</tr>
</tbody>
</table>

The extended mnemonics in Sections C.2.2 and C.3 require identification of a CR bit: if one of the CR field symbols is used, it must be multiplied by 4 and added to a bit-number-within-CR-field (value in the range 0-3, explicit or symbolic) and 32. The extended mnemonics in Sections C.2.3 and C.5 require identification of a CR field: if one of the CR field symbols is used, it must not be multiplied by 4 or added to 32. (For the extended mnemonics in Section C.2.3, the bit number within the CR field is part of the extended mnemonic. The programmer identifies the CR field, and the Assembler does the multiplication and addition required to produce a CR bit number for the BI field of the underlying basic mnemonic.)
C.2 Branch Mnemonics

The mnemonics discussed in this section are variations of the Branch Conditional instructions.

Note: bclr, bclrl, bcctr, and bcctrl each serve as both a basic and an extended mnemonic. The Assembler will recognize a bclr, bclrl, bcctr, or bcctrl mnemonic with three operands as the basic form, and a bclr, bclrl, bcctr, or bcctrl mnemonic with two operands as the extended form. In the extended form the BH operand is omitted and assumed to be 0b00. Similarly, for all the extended mnemonics described in Sections C.2.2 - C.2.4 that devolve to any of these four basic mnemonics the BH operand can either be coded or omitted. If it is omitted it is assumed to be 0b00.

C.2.1 BO and BI Fields

The 5-bit BO and BI fields control whether the branch is taken. Providing an extended mnemonic for every possible combination of these fields would be neither useful nor practical. The mnemonics described in Sections C.2.2 - C.2.4 include the most useful cases. Other cases can be coded using a basic Branch Conditional mnemonic (bc[l][a], bclrl[ ], bcctr[ ]) with the appropriate operands.

C.2.2 Simple Branch Mnemonics

Instructions using one of the mnemonics in Table 148 that tests a Condition Register bit specify the corresponding bit as the first operand. The symbols defined in Section C.1 can be used in this operand.

Notice that there are no extended mnemonics for relative and absolute unconditional branches. For these the basic mnemonics b, ba, bl, and bla should be used.

<td>bdzta</td>
</tr>
<tr>
<td>Decrement CTR, branch if CTR zero and CR[BI]=0</td>
<td>bdzf</td>
<td>bdzfa</td>
</tr>
</tbody>
</table>

Examples

1. Decrement CTR and branch if it is still nonzero (closure of a loop controlled by a count loaded into CTR).
   
   bdnz target  
   (equivalent to: bc 16,0,target)

2. Same as (1) but branch only if CTR is nonzero and condition in CR0 is "equal".
   
   bdnzt eq,target  
   (equivalent to: bc 8,2,target)

3. Same as (2), but "equal" condition is in CR5.
   
   bdnzt 4×cr5+eq,target  
   (equivalent to: bc 8,22,target)
4. Branch if bit 59 of CR is 0.
   bf 27,target  (equivalent to:  bc 4,27,target)

5. Same as (4), but set the Link Register. This is a form of conditional “call”.
   bfl 27,target  (equivalent to: bcl 4,27,target)

C.2.3 Branch Mnemonics Incorporating Conditions

In the mnemonics defined in Table 149, the test of a bit in a Condition Register field is encoded in the mnemonic.

Instructions using the mnemonics in Table 149 specify the CR field as an optional first operand. One of the CR field symbols defined in Section C.1 can be used for this operand. If the CR field being tested is CR Field 0, this operand need not be specified unless the resulting basic mnemonic is \texttt{bclr} or \texttt{bcctr} and the BH operand is specified.

A standard set of codes has been adopted for the most common combinations of branch conditions.

<table>
<thead>
<tr>

</tr>
<tr>
<td>Branch if unordered</td>
<td>bun</td>
<td>buna</td>
</tr>
<tr>
<td>Branch if not unordered</td>
<td>bnu</td>
<td>bunua</td>
</tr>
</tbody>
</table>

Examples

1. Branch if CR0 reflects condition "not equal".
   \texttt{bne \ target}  (equivalent to:  bc 4,2,target)

2. Same as (1), but condition is in CR3.
bne cr3,target (equivalent to: bc 4,14,target)

3. Branch to an absolute target if CR4 specifies “greater than”, setting the Link Register. This is a form of conditional “call”.
   bgta cr4,target (equivalent to: bcla 12,17,target)

4. Same as (3), but target address is in the Count Register.
   bgtcrn cr4 (equivalent to: bcctnl 12,17,0)

C.2.4 Branch Prediction

Software can use the “at” bits of Branch Conditional instructions to provide a hint to the processor about the behavior of the branch. If, for a given such instruction, the branch is almost always taken or almost always not taken, a suffix can be added to the mnemonic indicating the value to be used for the “at” bits.

+ Predict branch to be taken (at=0b11)
- Predict branch not to be taken (at=0b10)

Such a suffix can be added to any Branch Conditional mnemonic, either basic or extended, that tests either the Count Register or a CR bit (but not both). Assemblers should use 0b00 as the default value for the “at” bits, indicating that software has offered no prediction.

Examples

1. Branch if CR0 reflects condition “less than”, specifying that the branch should be predicted to be taken.
   blt+ target

2. Same as (1), but target address is in the Link Register and the branch should be predicted not to be taken.
   blttr-
C.3 Condition Register Logical Mnemonics

The Condition Register Logical instructions can be used to set (to 1), clear (to 0), copy, or invert a given Condition Register bit. Extended mnemonics are provided that allow these operations to be coded easily.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Extended Mnemonic</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td>Condition Register set</td>
<td>crset bx</td>
<td>creqv bx,bx,bx</td>
</tr>
<tr>
<td>Condition Register clear</td>
<td>crclr bx</td>
<td>crxor bx,bx,bx</td>
</tr>
<tr>
<td>Condition Register move</td>
<td>crmove bx,by</td>
<td>cror bx,by,by</td>
</tr>
<tr>
<td>Condition Register not</td>
<td>cmnot bx,by</td>
<td>cmor bx,by,by</td>
</tr>
</tbody>
</table>

The symbols defined in Section C.1 can be used to identify the Condition Register bits.

Examples
1. Set CR bit 57.
   
   crset 25 (equivalent to: creqv 25,25,25)

2. Clear the SO bit of CR0.
   
   crclr so (equivalent to: crxor 3,3,3)

3. Same as (2), but SO bit to be cleared is in CR3.
   
   crclr 4×cr3+so (equivalent to: crxor 15,15,15)

4. Invert the EQ bit.
   
   cmnot eq,eq (equivalent to: cmor 2,2,2)

5. Same as (4), but EQ bit to be inverted is in CR4, and the result is to be placed into the EQ bit of CR5.
   
   cmnot 4×cr5+eq,4×cr4+eq (equivalent to: cmor 22,18,18)

C.4 Subtract Mnemonics

C.4.1 Subtract Immediate

Although there is no "Subtract Immediate" instruction, its effect can be achieved by using an Add Immediate instruction with the immediate operand negated. Extended mnemonics are provided that include this negation, making the intent of the computation clearer.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Extended Mnemonic</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td>subi</td>
<td>Rx,Ry,value</td>
<td>addi Rx,Ry,-value</td>
</tr>
<tr>
<td>subis</td>
<td>Rx,Ry,value</td>
<td>addis Rx,Ry,-value</td>
</tr>
<tr>
<td>subic</td>
<td>Rx,Ry,value</td>
<td>addic Rx,Ry,-value</td>
</tr>
<tr>
<td>subic.</td>
<td>Rx,Ry,value</td>
<td>addic. Rx,Ry,-value</td>
</tr>
</tbody>
</table>

C.4.2 Subtract

The Subtract From instructions subtract the second operand (RA) from the third (RB). Extended mnemonics are provided that use the more "normal" order, in which the third operand is subtracted from the second. Both these mnemonics can be coded with a final "o" and/or "." to cause the OE and/or Rc bit to be set in the underlying instruction.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td>sub</td>
<td>Rx,Ry,Rz</td>
</tr>
<tr>
<td>subc</td>
<td>Rx,Ry,Rz</td>
</tr>
</tbody>
</table>
C.5 Compare Mnemonics

The L field in the fixed-point Compare instructions controls whether the operands are treated as 64-bit quantities or as 32-bit quantities. Extended mnemonics are provided that represent the L value in the mnemonic rather than requiring it to be coded as a numeric operand.

The BF field can be omitted if the result of the comparison is to be placed into CR Field 0. Otherwise the target CR field must be specified as the first operand. One of the CR field symbols defined in Section C.1 can be used for this operand.

Note: The Assembler will recognize a basic Compare mnemonic with three operands, and will generate the instruction with L=0. Thus the Assembler must require that the BF field, which normally can be omitted when CR Field 0 is the target, be specified explicitly if L is.

C.5.1 Doubleword Comparisons

<table>
<thead>
<tr>
<th>Operation</th>
<th>Extended Mnemonic</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td>Compare doubleword immediate</td>
<td>cmpdi bf,ra,si</td>
<td>cmpi 1,ra,si</td>
</tr>
<tr>

</tr>
<tr>
<td>Compare logical doubleword immediate</td>
<td>cmpldi bf,ra,ui</td>
<td>cmpli 1,ra,ui</td>
</tr>
<tr>
<td>Compare logical doubleword</td>
<td>cmpld bf,ra,rb</td>
<td>cmpl 1,ra,rb</td>
</tr>
</tbody>
</table>

Examples
1. Compare register Rx and immediate value 100 as unsigned 64-bit integers and place result into CR0.
   ```
   cmpldi Rx,100  
   ```
   (equivalent to:
   ```
   cmpi 0,1,Rx,100
   ```
2. Same as (1), but place result into CR4.
   ```
   cmpldi cr4,Rx,100
   ```
   (equivalent to:
   ```
   cmpli 4,1,Rx,100
   ```
3. Compare registers Rx and Ry as signed 64-bit integers and place result into CR0.
   ```
   cmpd Rx,Ry
   ```
   (equivalent to:
   ```
   cmp 0,1,Rx,Ry
   ```

C.5.2 Word Comparisons

<table>
<thead>
<tr>
<th>Operation</th>
<th>Extended Mnemonic</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td>Compare word immediate</td>
<td>cmpwi bf,ra,si</td>
<td>cmpi 0,ra,si</td>
</tr>
<tr>
<td>Compare word</td>

<td>cmp 0,ra,rb</td>
</tr>
<tr>
<td>Compare logical word immediate</td>
<td>cmplwi bf,ra,ui</td>
<td>cmpli 0,ra,ui</td>
</tr>
<tr>
<td>Compare logical word</td>
<td>cmplw bf,ra,rb</td>
<td>cmpl 0,ra,rb</td>
</tr>
</tbody>
</table>

Examples
1. Compare bits 32:63 of register Rx and immediate value 100 as signed 32-bit integers and place result into CR0.
   ```
   cmpwi Rx,100
   ```
   (equivalent to:
   ```
   cmpi 0,0,Rx,100
   ```
2. Same as (1), but place result into CR4.
   ```
   cmpwi cr4,Rx,100
   ```
   (equivalent to:
   ```
   cmpli 4,0,Rx,100
   ```
3. Compare bits 32:63 of registers Rx and Ry as unsigned 32-bit integers and place result into CR0.
   ```
   cmplw Rx,Ry
   ```
   (equivalent to:
   ```
   cmp 0,0,Rx,Ry
   ```
C.6 Trap Mnemonics

The mnemonics defined in Table 153 are variations of the Trap instructions, with the most useful values of TO represented in the mnemonic rather than specified as a numeric operand.

A standard set of codes has been adopted for the most common combinations of trap conditions.

<table>

Table 153: Trap mnemonics
Examples
1. Trap if register Rx is not 0.
   tdnei Rx,0 (equivalent to: tdi 24,Rx,0)
2. Same as (1), but comparison is to register Ry.
   tdne Rx,Ry (equivalent to: td 24,Rx,Ry)
3. Trap if bits 32:63 of register Rx, considered as a 32-bit quantity, are logically greater than 0x7FF.
   twlgti Rx,0x7FF (equivalent to: twi 1,Rx,0x7FF)
4. Trap unconditionally.
   trap (equivalent to: tw 31,0,0)
5. Trap unconditionally with immediate parameters Rx and Ry
   tdu Rx,Ry (equivalent to: td 31,Rx,Ry)

C.7 Integer Select Mnemonics

The mnemonics defined in Table 154, “Integer Select mnemonics,” on page 1018 are variations of the Integer Select instructions, with the most useful values of BC represented in the mnemonic rather than specified as a numeric operand.

<table>
<thead>
<tr>
<th>Code</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>lt</td>
<td>Less than</td>
</tr>
<tr>
<td>eq</td>
<td>Equal</td>
</tr>
<tr>
<td>gt</td>
<td>Greater than</td>
</tr>
</tbody>
</table>

These codes are reflected in the mnemonics shown in Table 154.

<table>
<thead>
<tr>
<th>Table 154: Integer Select mnemonics</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Select semantics</strong></td>
</tr>
<tr>
<td>-----------------------</td>
</tr>
<tr>
<td>Integer Select if less than</td>
</tr>
<tr>
<td>Integer Select if equal</td>
</tr>
<tr>
<td>Integer Select if greater than</td>
</tr>
</tbody>
</table>

Examples
1. Set register Rx to Ry if the LT bit is set in CR0, and to Rz otherwise.
   isellt Rx,Ry,Rz (equivalent to: isel Rx,Ry,Rz,0)
2. Set register Rx to Ry if the GT bit is set in CR0, and to Rz otherwise.
   iselgt Rx,Ry,Rz (equivalent to: isel Rx,Ry,Rz,1)
3. Set register Rx to Ry if the EQ bit is set in CR0, and to Rz otherwise.
   iseleq Rx,Ry,Rz (equivalent to: isel Rx,Ry,Rz,2)
C.8 Rotate and Shift Mnemonics

The Rotate and Shift instructions provide powerful and general ways to manipulate register contents, but can be difficult to understand. Extended mnemonics are provided that allow some of the simpler operations to be coded easily.

Mnemonics are provided for the following types of operation.

- **Extract** Select a field of n bits starting at bit position b in the source register; left or right justify this field in the target register; clear all other bits of the target register to 0.

- **Insert** Select a left-justified or right-justified field of n bits in the source register; insert this field starting at bit position b of the target register; leave other bits of the target register unchanged. (No extended mnemonic is provided for insertion of a left-justified field when operating on doublewords, because such an insertion requires more than one instruction.)

- **Rotate** Rotate the contents of a register right or left n bits without masking.

- **Shift** Shift the contents of a register right or left n bits, clearing vacated bits to 0 (logical shift).

- **Clear** Clear the leftmost or rightmost n bits of a register to 0.

- **Clear left and shift left** Clear the leftmost b bits of a register, then shift the register left by n bits. This operation can be used to scale a (known nonnegative) array index by the width of an element.

C.8.1 Operations on Doublewords

All these mnemonics can be coded with a final “.” to cause the Rc bit to be set in the underlying instruction.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Extended Mnemonic</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td>Extract and left justify immediate</td>
<td>extldi ra,rs,n,b (n &gt; 0)</td>
<td>rldicl ra,rs,b,n-1</td>
</tr>
<tr>
<td>Extract and right justify immediate</td>
<td>extrdi ra,rs,n,b (n &gt; 0)</td>
<td>rldicl ra,rs,b+n,64-n</td>
</tr>
<tr>
<td>Insert from right immediate</td>
<td>insrdi ra,rs,n,b (n &gt; 0)</td>
<td>rldimi ra,rs,64-(b+n),b</td>
</tr>
<tr>
<td>Rotate left immediate</td>
<td>rotldi ra,rs,n</td>
<td>rldicl ra,rs,n,0</td>
</tr>
<tr>
<td>Rotate right immediate</td>
<td>rotrdi ra,rs,n</td>
<td>rldicl ra,rs,64-n,0</td>
</tr>
<tr>
<td>Rotate left</td>
<td>rotld ra,rs,rb</td>
<td>rldcl ra,rs,rb,0</td>
</tr>
<tr>
<td>Shift left immediate</td>
<td>sldi ra,rs,n (n &lt; 64)</td>
<td>rldicl ra,rs,n,63-n</td>
</tr>
<tr>
<td>Shift right immediate</td>
<td>srdi ra,rs,n (n &lt; 64)</td>
<td>rldicl ra,rs,64-n,n</td>
</tr>
<tr>
<td>Clear left immediate</td>
<td>clrldi ra,rs,n (n &lt; 64)</td>
<td>rldicl ra,rs,0,n</td>
</tr>
<tr>
<td>Clear right immediate</td>
<td>clrrdi ra,rs,n (n &lt; 64)</td>
<td>rldicl ra,rs,0,63-n</td>
</tr>
<tr>
<td>Clear left and shift left immediate</td>
<td>clrldi ra,rs,b,n (n &lt;= b &lt; 64)</td>
<td>rldic ra,rs,n,b-n</td>
</tr>
</tbody>
</table>

Examples

1. Extract the sign bit (bit 0) of register Ry and place the result right-justified into register Rx.
   
   extrdi Rx,Ry,1,0 (equivalent to: rldicl Rx,Ry,1,63)

2. Insert the bit extracted in (1) into the sign bit (bit 0) of register Rz.
   
   insrdi Rz,Rx,1,0 (equivalent to: rldimi Rz,Rx,63,0)

3. Shift the contents of register Rx left 8 bits.
   
   sldi Rx,Rx,8 (equivalent to: rldicl Rx,Rx,8,55)

4. Clear the high-order 32 bits of register Ry and place the result into register Rx.
   
   clrrdi Rx,Ry,32 (equivalent to: rldicl Rx,Ry,0,32)
C.8.2 Operations on Words

All these mnemonics can be coded with a final "." to cause the Rc bit to be set in the underlying instruction. The operations as described above apply to the low-order 32 bits of the registers, as if the registers were 32-bit registers. The Insert operations either preserve the high-order 32 bits of the target register or place rotated data there; the other operations clear these bits.

### Examples

1. Extract the sign bit (bit 32) of register Ry and place the result right-justified into register Rx.
   
   ```
   extrwi Rx,Ry,1,0  
   ```
   
   (equivalent to:
   ```
   rlwinm Ra,Rs,b,0,n-1
   ```

2. Insert the bit extracted in (1) into the sign bit (bit 32) of register Rz.
   
   ```
   insrwi Rz,Rx,1,0  
   ```
   
   (equivalent to: 
   ```
   rlwimi Ra,Rs,32-b,b,(b+n)-1
   ```

3. Shift the contents of register Rx left 8 bits, clearing the high-order 32 bits.
   
   ```
   slwi Rx,Rx,8  
   ```
   
   (equivalent to: 
   ```
   rlwinm Ra,Rs,0,0,31
   ```

4. Clear the high-order 16 bits of the low-order 32 bits of register Ry and place the result into register Rx, clearing the high-order 32 bits of register Rx.
   
   ```
   clrlwi Rx,Ry,16  
   ```
   
   (equivalent to:
   ```
   rlwinm Ra,Rs,b-n,31-n
   ```

Examples

1. Copy the contents of register Rx to the XER.
   ```
   mtvxer Rx  
   ```

   (equivalent to: `mtspr 1,Rx`)
2. Copy the contents of the LR to register Rx.
   
   \texttt{mfr Rx} \quad \textit{(equivalent to: \texttt{mfsp}} \texttt{r Rx,8)}

3. Copy the contents of register Rx to the CTR.
   
   \texttt{mtctr Rx} \quad \textit{(equivalent to: \texttt{mtsp}} \texttt{r 9,Rx)}

\section*{C.10 Miscellaneous Mnemonics}

\subsection*{No-op}

Many Power ISA instructions can be coded in a way such that, effectively, no operation is performed. An extended mnemonic is provided for the preferred form of no-op. If an implementation performs any type of run-time optimization related to no-ops, the preferred form is the no-op that will trigger this.

\texttt{nop} \quad \textit{(equivalent to: \texttt{ori}} \texttt{0,0,0)}

For some uses of a no-op instruction, optimizations related to no-ops, such as removal from the execution stream, are not desireable. An extended mnemonic is provided for the executed form of no-op. This form of no-op will still consume execution resources.

\texttt{xnop} \quad \textit{(equivalent to: \texttt{xori}} \texttt{0,0,0)}

To avoid certain security vulnerabilities, it is sometimes desirable to constrain the order in which instructions are executed at certain points in a program. An extended mnemonic is provided for a form of the \textit{Or Immediate} instruction that serves this purpose. See Section 5.4.3 of Book III.

\texttt{exser} \quad \textit{(equivalent to: \texttt{ori}} \texttt{31,31,0)}

\subsection*{Load Immediate}

The \textit{addi} and \textit{addis} instructions can be used to load an immediate value into a register. Extended mnemonics are provided to convey the idea that no addition is being performed but merely data movement (from the immediate field of the instruction to a register).

Load a 16-bit signed immediate value into register Rx.

\texttt{li Rx,value} \quad \textit{(equivalent to: \texttt{addi}} \texttt{Rx,0,value)}

Load a 16-bit signed immediate value, shifted left by 16 bits, into register Rx.

\texttt{lis Rx,value} \quad \textit{(equivalent to: \texttt{addis}} \texttt{Rx,0,value)}

\subsection*{Load Next Instruction Address}

The \textit{addpcis} instruction can be used to load the next instruction address into a register. An extended mnemonics is provided to perform this operation.

\texttt{lnia Rx} \quad \textit{(equivalent to: \texttt{addpcis}} \texttt{Rx,0)}
Load Address

This mnemonic permits computing the value of a base-displacement operand, using the `addi` instruction which normally requires separate register and immediate operands.

\[ \text{la Rx,D(Ry)} \quad \text{(equivalent to: addi Rx,Ry,D)} \]

The `la` mnemonic is useful for obtaining the address of a variable specified by name, allowing the Assembler to supply the base register number and compute the displacement. If the variable \( v \) is located at offset \( D_v \) bytes from the address in register \( R_v \), and the Assembler has been told to use register \( R_v \) as a base for references to the data structure containing \( v \), then the following line causes the address of \( v \) to be loaded into register \( Rx \).

\[ \text{la Rx,v} \quad \text{(equivalent to: addi Rx,Rv,Dv)} \]

Move Register

Several Power ISA instructions can be coded in a way such that they simply copy the contents of one register to another. An extended mnemonic is provided to convey the idea that no computation is being performed but merely data movement (from one register to another).

The following instruction copies the contents of register \( Ry \) to register \( Rx \). This mnemonic can be coded with a final "." to cause the \( Rc \) bit to be set in the underlying instruction.

\[ \text{mr Rx,Ry} \quad \text{(equivalent to: or Rx,Ry,Ry)} \]

Complement Register

Several Power ISA instructions can be coded in a way such that they complement the contents of one register and place the result into another register. An extended mnemonic is provided that allows this operation to be coded easily.

The following instruction complements the contents of register \( Ry \) and places the result into register \( Rx \). This mnemonic can be coded with a final "." to cause the \( Rc \) bit to be set in the underlying instruction.

\[ \text{not Rx,Ry} \quad \text{(equivalent to: nor Rx,Ry,Ry)} \]

Move To/From Condition Register

This mnemonic permits copying the contents of the low-order 32 bits of a GPR to the Condition Register, using the same style as the `mfcr` instruction.

\[ \text{mtcr Rx} \quad \text{(equivalent to: mtcrf 0xFF,Rx)} \]

The following instructions may generate either the (old) `mtcrf` or `mfcr` instructions or the (new) `mtocrf` or `mfocrf` instruction, respectively, depending on the target machine type assembler parameter.

\[ \text{mtcrf FXM,Rx} \quad \text{mfcr Rx} \]

All three extended mnemonics in this subsection are being phased out. In future assemblers the form "mtcr Rx" may not exist, and the `mtcrf` and `mfcr` mnemonics may generate the old form instructions (with bit 11 = 0) regardless of the target machine type assembler parameter, or may cease to exist.
Book II:

Power ISA Virtual Environment Architecture
Chapter 1. Storage Model

1.1 Definitions

The following definitions, in addition to those specified in Book I, are used in this Book. In these definitions, "Load instruction" includes the Cache Management and other instructions that are stated in the instruction descriptions to be "treated as a Load", and similarly for "Store instruction".

- system
  A combination of processors, storage, and associated mechanisms that is capable of executing programs. Sometimes the reference to system includes services provided by the privileged software.

- main storage
  The level of storage hierarchy in which all storage state is visible to all processors and mechanisms in the system.

- normal memory
  Coherently-accessed, well-behaved regions of main storage that hold supervisor software and data and general purpose applications and data. This is in contrast with regions of main storage associated with accelerators or I/O interfaces or attached to other systems. Normal memory is assumed to have the following storage control attributes (see Section 1.6): not Write Through Required, not Caching Inhibited, Memory Coherence Required, and not Guarded.

- persistent storage
  Storage that retains its contents when power is removed, and is "behind" certain regions of main storage, that is not Caching Inhibited, in the sense that a store (to a location in such a region of main storage) will get to main storage before it gets to persistent storage.

- primary cache
  The level of cache closest to the processor.

- secondary cache
  After the primary cache, the next closest level of cache to the processor.

- instruction storage
  The view of storage as seen by the mechanism that fetches instructions.

- data storage
  The view of storage as seen by a Load or Store instruction.

- program order
  The execution of instructions in the order required by the sequential execution model. (See Section 2.2 of Book I.) A dcbz instruction that modifies storage which contains instructions has the same effect with respect to the sequential execution model as a Store instruction as described there.)

For the instructions and facilities defined in this Book, there are two additional exceptions to the sequential execution model that the processor obeys beyond those described in Section 2.2 of Book I.

- an event-based branch occurs (see Chapter 6)
- the BHRB is read (see Section 7.2)

- event-based exception
  An unusual condition, or external signal, that sets a status bit in the BESCR and may or may not cause an event-based branch, depending upon whether event-based branches are enabled.

- storage location
  A contiguous sequence of one or more bytes in storage. When used in association with a specific instruction or the instruction fetching mechanism, the length of the sequence of one or more bytes is typically implied by the operation. In other uses, it may refer more abstractly to a group of bytes which share common storage attributes.

- storage access
  An access to a storage location. There are three (mutually exclusive) kinds of storage access.

  - data access
    An access to the storage location specified by a Load or Store instruction, or, if the access is
performed “out-of-order” (see Section 6.5 of Book III), an access to a storage location as if it were the storage location specified by a Load or Store instruction.

- instruction fetch
  An access for the purpose of fetching an instruction.

- implicit access
  An access by the processor for the purpose of finding the address translation tables, translating an address, or recording reference and change information (see Book III).

- caused by, associated with
  - caused by
    A storage access is said to be caused by an instruction if the instruction is a Load or Store and the access (data access) is to the storage location specified by the instruction.
  - associated with
    A storage access is said to be associated with an instruction if the access is for the purpose of fetching the instruction (instruction fetch), or is a data access caused by the instruction, or is an implicit access that occurs as a side effect of fetching or executing the instruction.

- metadata
  Companion data associated with a storage location. In addition to the data that is loaded into a target register or stored from a source register, a storage location may be associated with additional control information. The granularity, meaning, and treatment of the control information may vary based on the type of storage access involved and on the state of the process making the access. Unless otherwise stated or obvious from context, loads ignore the metadata and stores zero the metadata.

Note that not all storage locations have associated metadata. The absence of associated metadata does not necessarily prevent successful completion of an instruction that specifies the treatment of metadata. Unless otherwise stated or obvious from context, metadata associated with a store is lost, and a load will have its metadata set to zero if the storage location has no associated metadata.

- prefetched instructions
  Instructions for which a copy of the instruction has been fetched from instruction storage, but the instruction has not yet been executed.

- uniprocessor
  A system that contains one processor.

- multiprocessor
  A system that contains two or more processors.

- shared storage multiprocessor
  A multiprocessor that contains some common storage, which all the processors in the system can access.

- performed
  A load or instruction fetch by a processor or mechanism (P1) is performed with respect to any processor or mechanism (P2) when the value to be returned by the load or instruction fetch can no longer be changed by a store by P2. A store by P1 is performed with respect to P2 when a load by P2 from the location accessed by the store will return the value stored (or a value stored subsequently). An instruction cache block invalidation by P1 is performed with respect to P2 when the instruction that requested the invalidation has caused the specified block, if present, to be made invalid in P2’s instruction cache, and similarly for a data cache block invalidation.

The preceding definitions apply regardless of whether P1 and P2 are the same entity.

- page (virtual page)
  2<sup>n</sup> contiguous bytes of storage aligned such that the effective address of the first byte in the page is an integral multiple of the page size for which protection and control attributes are independently specifiable and for which reference and change status are independently recorded.

- block
  The aligned unit of storage operated on by the Cache Management instructions. The size of an instruction cache block may differ from the size of a data cache block, and both sizes may vary between implementations. The maximum block size is equal to the minimum page size.

### 1.2 Introduction

The Power ISA User Instruction Set Architecture, discussed in Book I, defines storage as a linear array of bytes indexed from 0 to a maximum of 2<sup>64</sup>-1. Each byte is identified by its index, called its address, and each byte contains a value. This information is sufficient to allow the programming of applications that require no special features of any particular system environment. The Power ISA Virtual Environment Architecture, described herein, expands this simple storage model to include caches, virtual storage, and shared storage multiprocessors. The Power ISA Virtual Environment Architecture, in conjunction with services based on the Power ISA Operating Environment Architecture (see Book III) and provided by the operating system, permits explicit control of this expanded storage model. A sim-
ple model for sequential execution allows at most one storage access to be performed at a time and requires that all storage accesses appear to be performed in program order. In contrast to this simple model, the Power ISA specifies a relaxed model of storage consistency. In a multiprocessor system that allows multiple copies of a storage location, aggressive implementations of the architecture can permit intervals of time during which different copies of a storage location have different values. This chapter describes features of the Power ISA that enable programmers to write correct programs for this storage model.

1.3 Virtual Storage

The Power ISA system implements a virtual storage model for applications. This means that a combination of hardware and software can present a storage model that allows applications to exist within a “virtual” address space larger than either the effective address space or the real address space.

Each program can access 2^{64} bytes of “effective address” (EA) space, subject to limitations imposed by the operating system. In a typical Power ISA system, each program’s EA space is a subset of a larger “virtual address” (VA) space managed by the operating system.

Each effective address is translated to a real address (i.e., to an address of a byte in real storage or on an I/O device) before being used to access storage. The hardware accomplishes this, using the address translation mechanism described in Book III. The operating system manages the real (physical) storage resources of the system, by setting up the tables and other information used by the hardware address translation mechanism.

In general, real storage may not be large enough to map all the virtual pages used by the currently active applications. With support provided by hardware, the operating system can attempt to use the available real pages to map a sufficient set of virtual pages of the applications. If a sufficient set is maintained, “paging” activity is minimized. If not, performance degradation is likely.

The operating system can support restricted access to virtual pages (including read/write, read only, and no access; see Book III), based on system standards (e.g., program code might be read only) and application requests.

1.4 Single-Copy Atomicity

An access is single-copy atomic, or simply atomic, if it is always performed in its entirety with no visible fragmentation. Atomic accesses are thus serialized: each happens in its entirety in some order, even when that order is not specified in the program or enforced between processors.

The access caused by an instruction other than a Load/Store Multiple or Move Assist instruction is guaranteed to be atomic if the storage operand is not larger than a doubleword and is aligned (see Section 1.10.1 of Book I).

Quadword accesses with aligned storage operands are guaranteed to be atomic when caused by the following instructions:
- `lq`
- `stq`
- `lqarx`
- `stqcx`.

Quadword atomicity applies only to storage that is neither Write Through Required nor Caching Inhibited. The cases described above are the only cases in which the access to the storage operand is guaranteed to be atomic. For example, the access caused by the following instructions is not guaranteed to be atomic:
- any Load or Store instruction for which the storage operand is unaligned
- `lmw, stmw, lswi, lswx, stswi, stswx`
- `fldp, fldpx, stfdp, stfdpx`
- any Cache Management instruction

An access that is not atomic is performed as a set of smaller disjoint atomic accesses. If the non-atomic access is caused by an instruction other than a Load/Store Multiple or Move Assist instruction and one of the following conditions is satisfied, the non-atomic access is performed as described in the corresponding list item. The first list item matching a given situation applies.

- The storage operand is at least 16 bytes long and is doubleword-aligned:
  - the access is performed as a set of disjoint atomic accesses each of which consists of one or more aligned doublewords.
- The storage operand is at least eight bytes long and is word-aligned:
  - the access is performed as a set of disjoint atomic accesses each of which consists of one or more aligned words.
- The storage operand is at least four bytes long and is halfword-aligned:
  - the access is performed as a set of disjoint atomic accesses each of which consists of one or more aligned halfwords.

In all other cases the number, length, and alignment of the component disjoint atomic accesses are implementation-dependent. In all cases the relative order in which the component disjoint atomic accesses are performed is implementation-dependent.

The results for several combinations of loads and stores to the same or overlapping locations are described below.
1. When two processors perform atomic stores to locations that do not overlap, and no other stores are performed to those locations, the contents of those locations are the same as if the two stores were performed by a single processor.

2. When two processors perform atomic stores to the same storage location, and no other store is performed to that location, the contents of that location are the result stored by one of the processors.

3. When two processors perform stores that have the same target location and are not guaranteed to be atomic, and no other store is performed to that location, the result is some combination of the bytes stored by both processors.

4. When two processors perform stores to overlapping locations, and no other store is performed to those locations, the result is some combination of the bytes stored by the processors to the overlapping bytes. The portions of the locations that do not overlap contain the bytes stored by the processor storing to the location.

5. When a processor performs an atomic store to a location, a second processor performs an atomic load from that location, and no other store is performed to that location, the value returned by the load is the contents of the location before the store or the contents of the location after the store.

6. When a load and a store with the same target location can be performed simultaneously, and the accesses are not guaranteed to be atomic, and no other store is performed to that location, the value returned by the load is some combination of the contents of the location before the store and the contents of the location after the store.

1.5 Cache Model

A cache model in which there is one cache for instructions and another cache for data is called a “Harvard-style” cache. This is the model assumed by the Power ISA, e.g., in the descriptions of the Cache Management instructions in Section 4.3. Alternative cache models may be implemented (e.g., a “combined cache” model, in which a single cache is used for both instructions and data, or a model in which there are several levels of caches), but they support the programming model implied by a Harvard-style cache.

The processor is not required to maintain copies of storage locations in the instruction cache consistent with modifications to those storage locations (e.g., modifications caused by Store instructions).

A location in the data cache is considered to be modified in that cache if the location has been modified (e.g., by a Store instruction) and the modified data have not been written to main storage.

Cache Management instructions are provided so that programs can manage the caches when needed. For example, program management of the caches is needed when a program generates or modifies code that will be executed (i.e., when the program modifies data in storage and then attempts to execute the modified data as instructions). The Cache Management instructions are also useful in optimizing the use of memory bandwidth in such applications as graphics and numerically intensive computing. The functions performed by these instructions depend on the storage control attributes associated with the specified storage location (see Section 1.6, “Storage Control Attributes”).

The Cache Management instructions allow the program to do the following.

- invalidate the copy of storage in an instruction cache block (icbl)
- provide a hint that an instruction will probably soon be accessed from a specified instruction cache block (icbt)
- provide a hint that the program will probably soon access a specified data cache block (dcbt, dcbst)
- set the contents of a data cache block to zeros (dcbz)
- copy the contents of a modified data cache block to main storage (dcbst)
- copy the contents of a modified data cache block to main storage and make the copy of the block in the data cache invalid (dcbf or dcblf)

A write to main storage caused by a dcbst or dcbf instruction has updated main storage when a load by any given processor, that is satisfied from main storage from the location accessed by the write, will return the value written (or a value written or stored subsequently), and similarly for the store caused by a Store instruction.

1.6 Storage Control Attributes

Some operating systems may provide a means to allow programs to specify the storage control attributes described in this section. Because the support provided for these attributes by the operating system may vary between systems, the details of the specific system being used must be known before these attributes can be used.

Storage control attributes are associated with units of storage that are multiples of the page size. Each storage access is performed according to the storage control attributes of the specified storage location, as described below. The storage control attributes are the following.

- Write Through Required
- Caching Inhibited
Memory Coherence Required
Guarded

These attributes have meaning only when an effective address is translated by the processor performing the storage access.

Programming Note

The Write Through Required and Caching Inhibited attributes are mutually exclusive because, as described below, the Write Through Required attribute permits the storage location to be in the data cache while the Caching Inhibited attribute does not.

Storage that is Write Through Required or Caching Inhibited is not intended to be used for general-purpose programming. For example, the lbarx, llbarx, lwarx, ldarx, lg0rx, shtbcx, sthcx, stwbcx, stdcx, and stqcx instructions may cause the system data storage error handler to be invoked if they specify a location in storage having either of these attributes. To obtain the best performance across the widest range of implementations, storage that is Write Through Required or Caching Inhibited should be used only when the use of such storage meets specific functional or semantic needs or enables a performance optimization.

In the remainder of this section, "Load instruction" includes the Cache Management and other instructions that are stated in the instruction descriptions to be "treated as a Load" unless they are explicitly excluded, and similarly for "Store instruction".

1.6.1 Write Through Required

A store to a Write Through Required storage location is performed in main storage. A Store instruction that specifies a location in Write Through Required storage may cause additional locations in main storage to be accessed. If a copy of the block containing the specified location is retained in the data cache, the store is also performed in the data cache. The store does not cause the block to be considered to be modified in the data cache.

In general, accesses caused by separate Store instructions that specify locations in Write Through Required storage may be combined into one access. Such combining does not occur if the Store instructions are separated by a sync or eieio instruction.

1.6.2 Caching Inhibited

An access to a Caching Inhibited storage location is performed in main storage. A Load instruction that specifies a location in Caching Inhibited storage may cause additional locations in main storage to be accessed unless the specified location is also Guarded. An instruction fetch from Caching Inhibited storage may cause additional words in main storage to be accessed. No copy of the accessed locations is placed into the caches.

In general, non-overlapping accesses caused by separate Load instructions that specify locations in Caching Inhibited storage may be combined into one access, as may non-overlapping accesses caused by separate Store instructions that specify locations in Caching Inhibited storage. Such combining does not occur if the Load or Store instructions are separated by a sync instruction. Combining may also occur among such accesses from multiple processors that share a common memory interface. No combining occurs if the storage is also Guarded.

Programming Note

None of the memory barrier instructions prevent the combining of accesses from different processors. The Guarded storage attribute must be used in combination with Caching Inhibited to prevent such combining.

1.6.3 Memory Coherence Required

An access to a Memory Coherence Required storage location is performed coherently, as follows.

Memory coherence refers to the ordering of stores to a single location. Atomic stores to a given location are coherent if they are serialized in some order, and no processor or mechanism is able to observe any subset of those stores as occurring in a conflicting order. This serialization order is an abstract sequence of values; the physical storage location need not assume each of the values written to it. For example, a processor may update a location several times before the value is written to physical storage. The result of a store operation is not available to every processor or mechanism at the same instant, and it may be that a processor or mechanism observes only some of the values that are written to a location. However, when a location is accessed atomically and coherently by all processors and mechanisms, the sequence of values loaded from the location by any processor or mechanism during any interval of time forms a subsequence of the sequence of values that the location logically held during that interval. That is, a processor or mechanism can never load a “newer” value first and then, later, load an “older” value.

Memory coherence is managed in blocks called coherence blocks. Their size is implementation-dependent, but is larger than a word and is usually the size of a cache block.

For storage that is not Memory Coherence Required, software must explicitly manage memory coherence to...
the extent required by program correctness. The operations required to do this may be system-dependent.

Because the Memory Coherence Required attribute for a given storage location is of little use unless all processors that access the location do so coherently, in statements about Memory Coherence Required storage elsewhere in this document it is generally assumed that the storage has the Memory Coherence Required attribute for all processors that access it.

### Programming Note

Operating systems that allow programs to request that storage not be Memory Coherence Required should provide services to assist in managing memory coherence for such storage, including all system-dependent aspects thereof.

In most systems the default is that all storage is Memory Coherence Required. For some applications in some systems, software management of coherence may yield better performance. In such cases, a program can request that a given unit of storage not be Memory Coherence Required, and can manage the coherence of that storage by using the `sync` instruction, the `Cache Management` instructions, and services provided by the operating system.

1.6.4 Guarded

A data access to a Guarded storage location is performed only if either (a) the access is caused by an instruction that is known to be required by the sequential execution model, or (b) the access is a load and the storage location is already in a cache. If the storage is also Caching Inhibited, only the storage location specified by the instruction is accessed; otherwise any storage location in the cache block containing the specified storage location may be accessed.

Except in ultravisor or hypervisor real addressing mode, instructions are not fetched from storage that is Guarded. Except in these addressing modes, if the instruction addressed by the current instruction address is in such storage, the system instruction storage error handler is invoked (see Section 7.5.5 of Book III).

---

1.7 Shared Storage

This architecture supports the sharing of storage between programs, between different instances of the same program, and between processors and other mechanisms. It also supports access to a storage location by one or more programs using different effective addresses. All these cases are considered storage sharing. Storage is shared in blocks that are an integral number of pages.

When the same storage location has different effective addresses, the addresses are said to be aliases. Each application can be granted separate access privileges to aliased pages.

1.7.1 Storage Access Ordering

The storage model for the ordering of storage accesses is weakly consistent. This model provides an opportunity for improved performance over a model that has stronger consistency rules, but places the responsibility on the program to ensure that ordering or synchronization instructions are properly placed when storage is shared by two or more programs.

The order in which the processor performs storage accesses, the order in which those accesses are performed with respect to another processor or mechanism, and the order in which those accesses are performed in main storage may all be different. Several means of enforcing an ordering of storage accesses are provided to allow programs to share storage with other programs, or with mechanisms such as I/O devices. These means are listed below. The phrase "to the extent required by the associated Memory
Coherence Required attributes” refers to the Memory Coherence Required attribute, if any, associated with each access.

- If two Store instructions or two Load instructions specify storage locations that are both Caching Inhibited and Guarded, the corresponding storage accesses are performed in program order with respect to any processor or mechanism.

- If a Load instruction depends on the value returned by a preceding Load instruction (because the value is used to compute the effective address specified by the second Load), the corresponding storage accesses are performed in program order with respect to any processor or mechanism to the extent required by the associated Memory Coherence Required attributes. This applies even if the dependency has no effect on program logic (e.g., the value returned by the first Load is ANDed with zero and then added to the effective address specified by the second Load).

- When a processor (P1) executes a Synchronize or eieio instruction a memory barrier is created, which orders applicable storage accesses pairwise, as follows. Let A be a set of storage accesses that includes all storage accesses associated with instructions preceding the barrier-creating instruction, and let B be a set of storage accesses that includes all storage accesses associated with instructions following the barrier-creating instruction. For each applicable pair $a_i,b_j$ of storage accesses such that $a_i$ is in A and $b_j$ is in B, the memory barrier ensures that $a_i$ will be performed with respect to any processor or mechanism, to the extent required by the associated Memory Coherence Required attributes, before $b_j$ is performed with respect to that processor or mechanism.

The ordering done by a memory barrier is said to be “cumulative” if it also orders storage accesses that are performed by processors and mechanisms other than P1, as follows.

- A includes all applicable storage accesses by any such processor or mechanism that have been performed with respect to P1 before the memory barrier is created.

- B includes all applicable storage accesses by any such processor or mechanism that are performed after a Load instruction executed by that processor or mechanism has returned the value stored by a store that is in B.

No ordering should be assumed among the storage accesses caused by a single instruction (i.e., by an instruction for which the access is not atomic), and no means are provided for controlling that order.
Programming Note

Because stores cannot be performed “out-of-order” (see Book III), if a Store instruction depends on the value returned by a preceding Load instruction (because the value returned by the Load is used to compute either the effective address specified by the Store or the value to be stored), the corresponding storage accesses are performed in program order. The same applies if whether the Store instruction is executed depends on a conditional Branch instruction that in turn depends on the value returned by a preceding Load instruction.

Because an isync instruction prevents the execution of instructions following the isync until instructions preceding the isync have completed, if an isync follows a conditional Branch instruction that depends on the value returned by a preceding Load instruction, the load on which the Branch depends is performed before any loads caused by instructions following the isync. This applies even if the effects of the “dependency” are independent of the value loaded (e.g., the value is compared to itself and the Branch tests the EQ bit in the selected CR field), and even if the branch target is the sequentially next instruction.

With the exception of the cases described above and earlier in this section, data dependencies and control dependencies do not order storage accesses. Examples include the following.

- If a Load instruction specifies the same storage location as a preceding Store instruction and the location is in storage that is not Caching Inhibited, the load may be satisfied from a “store queue” (a buffer into which the processor places stored values before presenting them to the storage subsystem), and not be visible to other processors and mechanisms. A consequence is that if a subsequent Store depends on the value returned by the Load, the two stores need not be performed in program order with respect to other processors and mechanisms.

- Because a Store Conditional instruction may complete before its store has been performed, a conditional Branch instruction that depends on the CR0 value set by a Store Conditional instruction does not order the Store Conditional’s store with respect to storage accesses caused by instructions that follow the Branch.

- Because processors may predict branch target addresses and branch condition resolution, control dependencies (e.g., branches) do not order storage accesses except as described above. For example, when a subroutine returns to its caller the return address may be predicted, with the result that loads caused by instructions at or after the return address may be performed before the load that obtains the return address is performed.

Because processors may implement nonarchitected duplicates of architected resources (e.g., GPRs, CR fields, and the Link Register), resource dependencies (e.g., specification of the same target register for two Load instructions) do not order storage accesses.

Examples of correct uses of dependencies, sync and lwsync to order storage accesses can be found in Appendix B. “Programming Examples for Sharing Storage” on page 1107.

Because the storage model is weakly consistent, the sequential execution model as applied to instructions that cause storage accesses guarantees only that those accesses appear to be performed in program order with respect to the processor executing the instructions. For example, an instruction may complete, and subsequent instructions may be executed, before storage accesses caused by the first instruction have been performed. However, for a sequence of atomic accesses to the same storage location, if the location is in storage that is Memory Coherence Required the definition of coherence guarantees that the accesses are performed in program order with respect to any processor or mechanism that accesses the location coherently, and similarly if the location is in storage that is Caching Inhibited.

Because accesses to storage that is Caching Inhibited are performed in main storage, memory barriers and dependencies on Load instructions order such accesses with respect to any processor or mechanism even if the storage is not Memory Coherence Required.
1.7.1.1 Storage Ordering of Copy/Paste-Initiated Data Transfers

The Copy-Paste Facility (see Section 4.4) uses pairs of instructions to initiate 128-byte data transfers. They are referred to as "data transfers" to differentiate them from the "normal" storage accesses caused by or associated with loads, stores, and instructions that are treated as loads and stores. In the absence of barriers, the relative ordering among adjacent data transfers or data transfers and storage accesses is not defined, and the sequential execution model and coherence-required ordering relationships do not apply. To establish order between adjacent data transfers or between data transfers and storage accesses, `hwsync` must be used. See the description of the `Synchronize` instruction in Section 4.6.3 for more information.

1.7.1.2 Storage Ordering of Stores to Persistent Storage

A location in a region of main storage that is backed by persistent storage is considered to be modified relative to persistent storage if the location has been modified in main storage (e.g., by a Store instruction) and the modified data have not been written to persistent storage. A store has updated persistent storage when a load by any given processor, from the location accessed by the store, would return the value stored (or a value stored subsequently) if system power were lost temporarily between the time the store has updated persistent storage and the time the load is performed. A store may update persistent storage significantly later than it updates main storage. The `dcbstps` (data cache block store to persistent storage) and `dcbffsp` (data cache block flush to persistent storage) instructions can be used to write modified locations in a block to persistent storage (and to perform the functions of Data Cache Block Store and Data Cache Block Flush respectively). The `phwsync` (persistent heavy-weight sync) and `plwsync` (persistent lightweight sync) instructions can be used to establish order for these writes to persistent storage. A store may update persistent storage even in the absence of `dcbstps` and `dcbffps` instructions targeting the cache block(s) affected by the store. See Section 4.3.2 and Section 4.6.3 for more information.

Except in this section and in other material dealing with persistent storage, references to the storage subsystem in this document assume system power is not lost unless otherwise stated or obvious from context.

Programming Note

It may be helpful to think of a `copy/paste`, pair sending the real storage addresses of the 128-byte source and destination to an asynchronous data transfer engine completely separate from the processor that is executing the `copy` and `paste` instructions. The data transfers collect in the engine's queue. The engine may perform the data transfers in any order, and with the only relative timing relationship to adjacent transfers and accesses being determined by `hwsync`.

Programming Note

The first example below illustrates cumulative ordering of storage accesses preceding a memory barrier, and the second illustrates cumulative ordering of storage accesses following a memory barrier. Assume that locations X, Y, and Z initially contain the value 0.

Example 1:
Processor A:
stores the value 1 to location X

Processor B:
loads from location X obtaining the value 1, executes a `sync` instruction, then stores the value 2 to location Y

Processor C:
loads from location Y obtaining the value 2, executes a `sync` instruction, then loads from location X

Example 2:
Processor A:
stores the value 1 to location X, executes a `sync` instruction, then stores the value 2 to location Y

Processor B:
loops loading from location Y until the value 2 is obtained, then stores the value 3 to location Z

Processor C:
loads from location Z obtaining the value 3, executes a `sync` instruction, then loads from location X

In both cases, cumulative ordering dictates that the value loaded from location X by processor C is 1.
1.7.1.3 Storage Ordering of I/O Accesses

A “coherence domain” consists of all processors and all interfaces to main storage. Memory reads and writes initiated by mechanisms outside the coherence domain are performed within the coherence domain in the order in which they enter the coherence domain and are performed as coherent accesses.

1.7.2 Atomic Update

The Load And Reserve and Store Conditional instructions together permit atomic update of a shared storage location. There are byte, halfword, word, doubleword, and quadword forms of each of these instructions. Described here is the operation of the word forms \textit{lwarx} and \textit{stwcx}; operation of the byte, halfword, doubleword, and quadword forms \textit{lbax}, \textit{stbx}, \textit{lwax}, \textit{stdcx}, \textit{ldcx}, \textit{ldcx}, and \textit{stqcx} is the same except for obvious substitutions.

The \textit{lwarx} instruction is a load from a word-aligned location that has two side effects. Both of these side effects occur at the same time that the load is performed.

1. A reservation for a subsequent \textit{stwcx} instruction is created.

2. The memory coherence mechanism is notified that a reservation exists for the storage location specified by the \textit{lwarx}.

The \textit{stwcx} instruction is a store to a word-aligned location that is conditioned on the existence of the reservation created by the \textit{lwarx} and on whether the same storage location is specified by both instructions. To emulate an atomic operation with these instructions, it is necessary that both the \textit{lwarx} and the \textit{stwcx} specify the same storage location.

A \textit{stwcx} performs a store to the target storage location only if the reservation created by the \textit{lwarx} still exists at the time the \textit{stwcx} is executed, and only if the storage locations specified by the two instructions are in the same aligned block of real storage whose size is the smallest real page size supported by the implementation. The remainder of this paragraph assumes that these two conditions are satisfied. If the storage locations specified by the two instructions differ, or if a \textit{Store Conditional} instruction is used with a preceding \textit{Load And Reserve} instruction that has a different storage operand length (e.g., \textit{stwcx} with \textit{ldarx}), whether the store is performed is undefined. Otherwise the store is performed.

A \textit{stwcx} that performs its store is said to “succeed”.

Examples of the use of \textit{lwarx} and \textit{stwcx} are given in Appendix B. “Programming Examples for Sharing Storage” on page 1107.

A successful \textit{stwcx} to a given location may complete before its store has been performed with respect to other processors and mechanisms. As a result, a subsequent load or \textit{lwarx} from the given location by another processor may return a “stale” value. However, a subsequent \textit{lwarx} from the given location by the other processor followed by a successful \textit{stwcx} by that processor is guaranteed to have returned the value stored by the first processor’s \textit{stwcx}. (In the absence of other stores to the given location).
**Programming Note**

If a virtual address is reassigned to a different real page, a reservation established at the virtual address before the reassignment will not be cleared by a store to the new real page by some other processor or mechanism. (As described in Section 1.7.2.1, reservations are held on real addresses.) If **Store Conditional** instructions did not suppress the store when the storage location specified by the **Store Conditional** instruction is in a different real page from the storage location specified by the corresponding **Load And Reserve** instruction, such virtual address reassignment could permit a **Store Conditional** instruction that specifies the same virtual address as the corresponding **Load And Reserve** instruction, and logically should fail because the other processor or mechanism stored to the virtual address, to succeed.

This real address checking cannot detect that the virtual page in which the reservation was established has been moved to a new real page and back again to the original real page that was accessed by the **Load And Reserve** instruction. It also cannot detect that the real address of the storage location specified by a **Store Conditional** instruction is the same as the real address of the reservation, or is in the same real page as the reservation, only because the virtual page containing the storage location specified by the **Store Conditional** instruction has been moved to the real page that was accessed by the corresponding **Load And Reserve** instruction. Privileged software that moves a virtual page should clear the reservation on the processor it is running on in order to ensure that a **Store Conditional** instruction executed by that processor does not succeed in these cases. (If the software that moves the virtual page uses **Load And Reserve** and **Store Conditional** for its own purposes, the clearing of the original reservation will happen naturally. The stores that occur naturally as part of moving the virtual page will cause any reservations, held by other processors, in the target real page to be cleared.)

**1.7.2.1 Reservations**

The ability to emulate an atomic operation using **lwarx** and **stwcx**, is based on the conditional behavior of **stwcx**, the reservation created by **lwarx**, and the clearing of that reservation if the target storage location is modified by another processor or mechanism before the **stwcx** performs its store.

A reservation is held on an aligned unit of real storage called a reservation granule. The size of the reservation granule is \(2^n\) bytes, where \(n\) is implementation-dependent but is always at least 4 (thus the minimum reservation granule size is a quadword), and where \(2^n\) is not larger than the smallest real page size supported by the implementation. The reservation granule associated with effective address EA contains the real address to which EA maps. ("real_addr(EA)" in the RTL for the **Load And Reserve** and **Store Conditional** instructions stands for "real address to which EA maps"). The reservation also has an associated length, which is equal to the storage operand length, in bytes, of the **Load And Reserve** instruction that established the reservation.

A processor has at most one reservation at any time. A reservation is established by executing a **lbarx**, **lharx**, **lwarx**, **ldarx**, or **ldarx** instruction, as described in item 1 below, and is lost or may be lost, depending on the item, if any of the following occur. Items 1-8 apply only if the relevant access is performed. (For example, an access that would ordinarily be caused by an instruction might not be performed if the instruction causes the system error handler to be invoked.)

1. The processor holding the reservation executes another **lbarx**, **lbarx**, **lwarx**, **ldarx**, or **ldarx**: this clears the first reservation and establishes a new one.

2. The processor holding the reservation executes any **stbcx**, **sthcx**, **stwcx**, **stdcx**, or **stqcx**, regardless of whether the specified address matches the address specified by the **lbarx**, **lbarx**, **lwarx**, **ldarx**, or **ldarx** that established the reservation, and regardless of whether the storage operands lengths of the two instructions are the same.

3. The processor holding the reservation executes an **AMO** that updates the same reservation granule: whether the reservation is lost is undefined.

4. Some other processor executes a **Store or dcbz** that specifies a location in the same reservation granule.

5. Some other processor executes a **dcbstx**, or **dcbst** that specifies a location in the same reservation granule: whether the reservation is lost is undefined. (For a **dcbstx** instruction that specifies a data stream, "location" in the preceding sentence includes all locations in the data stream.)

6. Any processor modifies a Reference or Change bit in the same reservation granule: the reservation is lost if the modification is atomic; otherwise whether the reservation is lost is undefined. (See Section 6.7.12 of Book III)

7. Some mechanism other than a processor modifies a storage location in the same reservation granule.

8. An interrupt (see Book III) occurs on the processor holding the reservation: the interrupt itself does not clear the reservation, but system software invoked by the interrupt may clear the reservation.

9. Implementation-specific characteristics of the coherence mechanism cause the reservation to be lost.
The reservation is also used by the `waitrsv` instruction (see Section 4.6.4).

**Virtualized Implementation Note**

A reservation may be lost if:
- Software executes a privileged instruction or utilizes a privileged facility
- Software accesses storage not intended for general-purpose programming

**Programming Note**

One use of `lwarx` and `stwcx` is to emulate a “Compare and Swap” primitive like that provided by the IBM System/370 Compare and Swap instruction; see Section B.1, “Atomic Update Primitives” on page 1107. A System/370-style Compare and Swap checks only that the old and current values of the word being tested are equal, with the result that programs that use such a Compare and Swap to control a shared resource can err if the word has been modified and the old value subsequently restored. The combination of `lwarx` and `stwcx` improves on such a Compare and Swap, because the reservation reliably binds the `lwarx` and `stwcx` together. The reservation is always lost if the word is modified by another processor or mechanism between the `lwarx` and `stwcx`, so the `stwcx` never succeeds unless the word has not been stored into (by another processor or mechanism) since the `lwarx`.

**Programming Note**

In general, programming conventions must ensure that `lwarx` and `stwcx` specify addresses that match; a `stwcx` should be paired with a specific `lwarx` to the same storage location. Situations in which a `stwcx` may erroneously be issued after some `lwarx` other than that with which it is intended to be paired must be scrupulously avoided. For example, there must not be a context switch in which the processor holds a reservation in behalf of the old context, and the new context resumes after a `lwarx` and before the paired `stwcx`. The `stwcx` in the new context might succeed, which is not what was intended by the programmer. Such a situation must be prevented by executing a `stbcx`, `stthcx`, `stwcx`, `stdcx`, or `stqcx` that specifies a dummy writable aligned location as part of the context switch; see Section 7.4.3 of Book III.

**Programming Note**

Because the reservation is lost if another processor stores anywhere in the reservation granule, lock words (or bytes, halfwords, or doublewords) should be allocated such that few such stores occur, other than perhaps to the lock word itself. (Stores by other processors to the lock word result from contention for the lock, and are an expected consequence of using locks to control access to shared storage: stores to other locations in the reservation granule can cause needless reservation loss.) Such allocation can most easily be accomplished by allocating an entire reservation granule for the lock and wasting all but one word. Because reservation granule size is implementation-dependent, portable code must do such allocation dynamically.

Similar considerations apply to other data that are shared directly using `lwarx` and `stwcx` (e.g., pointers in certain linked lists; see Section B.3, “List Insertion” on page 1111).

### 1.7.2.2 Forward Progress

Forward progress in loops that use `lwarx` and `stwcx` is achieved by a cooperative effort among hardware, system software, and application software.

The architecture guarantees that when a processor executes an `lwarx` to obtain a reservation for location X and then an `stwcx` to store a value to location X, either

1. the `stwcx` succeeds and the value is written to location X, or
2. the `stwcx` fails because some other processor or mechanism modified location X, or
3. the `stwcx` fails because the processor’s reservation was lost for some other reason.

In Cases 1 and 2, the system as a whole makes progress in the sense that some processor successfully modifies location X. Case 3 covers reservation loss required for correct operation of the rest of the system. This includes cancellation caused by some other processor or mechanism writing elsewhere in the reservation granule, cancellation caused by the operating system in managing certain limited resources such as real storage, and cancellation caused by any of the other effects listed in see Section 1.7.2.1.

An implementation may make a forward progress guarantee, defining the conditions under which the system as a whole makes progress. Such a guarantee must specify the possible causes of reservation loss in Case 3. While the architecture alone cannot provide such a guarantee, the characteristics listed in Cases 1 and 2 are necessary conditions for any forward progress
guarantee. An implementation and operating system can build on them to provide such a guarantee.

---

**Virtualized Implementation Note**

On a virtualized implementation, Case 3 includes reservation loss caused by the virtualization software. Thus, on a virtualized implementation, a reservation may be lost at any time without apparent cause. The virtualization software participates in any forward progress assurances, as described above.

---

**Programming Note**

The architecture does not include a “fairness guarantee”. In competing for a reservation, two processors can indefinitely lock out a third.

---

### 1.8 Instruction Storage

The instruction execution properties and requirements described in this section, including its subsections, apply only to instruction execution that is required by the sequential execution model.

In this section, including its subsections, it is assumed that all instructions for which execution is attempted are in storage that is not Caching Inhibited and (unless instruction address translation is disabled; see Book III) is not Guarded, and from which instruction fetching does not cause the system error handler to be invoked (e.g., from which instruction fetching is not prohibited by the "address translation mechanism" or the "storage protection mechanism"; see Book III).

---

**Programming Note**

The results of attempting to execute instructions from storage that does not satisfy this assumption are described in Section 1.6.2 and Section 1.6.4 of this Book and in Book III.

---

The instruction cache is not necessarily kept consistent with the data cache or with main storage. It is the responsibility of software to ensure that instruction storage is consistent with data storage when such consistency is required for program correctness.

After one or more bytes of a storage location have been modified and before an instruction located in that storage location is executed, software must execute the appropriate sequence of instructions to make instruction storage consistent with data storage. Otherwise the result of attempting to execute the instruction is boundedly undefined except as described in Section 1.8.1, "Concurrent Modification and Execution of Instructions" on page 1043.
Programming Note

Following are examples of how to make instruction storage consistent with data storage. Because the optimal instruction sequence to make instruction storage consistent with data storage may vary between systems, many operating systems will provide a system service to perform this function.

Case 1: The given program does not modify instructions executed by another program nor does another program modify the instructions executed by the given program.

Assume that location X previously contained the instruction A0; the program modified one or more bytes of that location such that, in data storage, the location contains the instruction A1; and location X is wholly contained in a single cache block. The following instruction sequence will make instruction storage consistent with data storage such that if the isync was in location X-4, the instruction A1 in location X would be executed immediately after the isync.

```
dcbst X #copy the block in main storage
csync #order copy before invalidation
icbi X #invalidate copy in instr cache
isync #order invalidation before store
    # to flag
stw r0,flag #set flag indicating instruction
    # storage is now consistent
```

Case 2: One or more programs execute the instructions that are concurrently being modified by another program.

Assume program A has modified the instruction at location X and other programs are waiting for program A to signal that the new instruction is ready to execute. The following instruction sequence will make instruction storage consistent with data storage and then set a flag to indicate to the waiting programs that the new instruction can be executed.

```
li r0,1 #put a 1 value in r0
dcbst X #copy the block in main storage
csync #order copy before invalidation
icbi X #invalidate copy in instr cache
csync #order invalidation before store
    # to flag
stw r0,flag #set flag indicating instruction
    # storage is now consistent
```

The following instruction sequence, executed by the waiting program, will prevent the waiting programs from executing the instruction at location X until location X in instruction storage is consistent with data storage, and then will cause any prefetched instructions to be discarded.

```
lwz r0,flag #loop until flag = 1 (when 1 is loaded, location X in inst'n
    be stored is consistent with
    # location X in data storage)
    # to flag
icbi X #invalidate copy in instr cache
icbi X #invalidate copy in instr cache
csync #order invalidation before store
    # to flag
```

In the preceding instruction sequence any context synchronizing instruction (e.g., rfid) can be used instead of isync. (For Case 1 only isync can be used.)

For both cases, if two or more instructions in separate data cache blocks have been modified, the dcbst instruction in the examples must be replaced by a sequence of dcbst instructions such that each block containing the modified instructions is copied back to main storage. Similarly, for icbi the sequence must invalidate each instruction cache block containing a location of an instruction that was modified. The sync instruction that appears above between “dcbst X” and “icbi X” would be placed between the sequence of dcbst instructions and the sequence of icbi instructions.
1.8.1 Concurrent Modification and Execution of Instructions

The phrase “concurrent modification and execution of instructions” (CMODX) refers to the case in which a processor fetches and executes an instruction from instruction storage which has not been made consistent with data storage. This section describes the only case in which executing this instruction under these conditions produces defined results.

In the remainder of this section the following terminology is used.

- Location X is an arbitrary four-byte word-aligned storage location.
- \( X_0 \) is the value of the contents of location X for which software has made the location X in instruction storage consistent with data storage.
- \( X_1, X_2, \ldots, X_n \) are the sequence of the first n values occupying location X after \( X_0 \).
- \( X_n \) is the first value of X subsequent to \( X_0 \) for which software has again made instruction storage consistent with data storage.

- The “patch class” of words consists of the following.
  - the I-form Branch instruction \((b[l][a])\)
  - the preferred no-op instruction \((ori 0,0,0)\)
  - the prefix of the Prefixed No-op instruction \((pnop)\)
  - the D-form and X-form Trap instructions for which \( TO = 0b11111 \)

- The “instruction from location X” includes both the case of a word instruction contained in location X and the case of a prefixed instruction for which the prefix is contained in location X.

If the instruction from location X is executed after the copy of location X in instruction storage is made consistent for the value \( X_0 \) and before it is made consistent for the value \( X_n \), the results of executing the instruction are defined if and only if the following conditions are satisfied.

1. The stores that place the values \( X_1, \ldots, X_n \) into location X are atomic stores that modify all four bytes of location X.
2. The sequence of \( X_i \) values is one of two types:
   - any sequence in which each \( X_i \) is a patch class word, or
   - any sequence that is comprised of exactly two unique word values, at least one of which is a patch class word.
3. If a sequence of \( X_i \) values contains a prefix, the only word instructions the sequence can contain are the patch class Branch and patch class Trap instructions. In this use, the target of the Branch instruction must not be the word following the Branch instruction.
4. Location X is in storage that is Memory Coherence Required.

Programming Note

The architecture does not support CMODX modification of an entire prefixed instruction because it may be unaligned and therefore impossible to modify atomically. Furthermore, no need has arisen to motivate the creation of special cases where it must work. The architecture also does not support CMODX modification of the suffix of a prefixed instruction.

If these conditions are satisfied, each execution of an instruction from location X will use some \( X_i \), \( 0 \leq i \leq n \). The value of the ordinate \( i \) associated with each value executed may be different and the sequence of ordinates \( i \) associated with a sequence of values executed is not constrained, (e.g., a valid sequence of executions of the instruction from location X could use the sequence \( X_i, X_{i+2}, \) then \( X_{i+1} \)). If these conditions are not satisfied, the results of each such execution of an instruction from location X are boundedly undefined, and may include causing inconsistent information to be presented to the system error handler.

Programming Note

An example of how failure to satisfy the requirements given above can cause inconsistent information to be presented to the system error handler is as follows. If the value \( X_0 \) (an illegal instruction) is executed, causing the system illegal instruction handler to be invoked, and before the error handler can load \( X_0 \) into a register, \( X_0 \) is replaced with \( X_1 \), an Add Immediate instruction, it will appear that a legal instruction caused an illegal instruction exception.
It is possible to apply a patch or to instrument a given program without the need to suspend or halt the program. This can be accomplished by modifying the example shown in the Programming Note at the end of Section 1.8 where one program is creating instructions to be executed by one or more other programs.

In place of the Store to a flag to indicate to the other programs that the code is ready to be executed, the program that is applying the patch would replace an instruction in the original program with an I-form Branch instruction that would cause any program executing the Branch to branch to the newly created code. The first instruction in the newly created code must be an isync, which will cause any prefetched instructions to be discarded, ensuring that the execution is consistent with the newly created code. The instruction storage location containing the isync instruction in the patch area must be consistent with data storage with respect to the processor that will execute the patched code before the Store which stores the new Branch instruction is performed.

The ability to modify instructions that may be being executed provides opportunities for significant performance benefits in interpretive environments (e.g., Java), and can be used to instrument code dynamically to isolate critical hardware and software bugs.
In this section, "Load instruction" includes the Cache Management and other instructions that are stated in the instruction descriptions to be “treated as a Load”, and similarly for "Store instruction".

The following instructions are never restarted after having accessed any portion of the storage operand (unless the instruction causes a “Data Address Watchpoint match”, for which the corresponding rules are given in Book III).

1. A Store instruction that causes an atomic access
2. A Load instruction that causes an atomic access to storage that is both Caching Inhibited and Guarded

Any other Load or Store instruction may be partially executed and then aborted after having accessed a portion of the storage operand, and then re-executed (i.e., restarted, by the processor or the operating system). If an instruction is partially executed, the contents of registers are preserved to the extent that the correct result will be produced when the instruction is re-executed. Additional restrictions on the partial execution of instructions are described in Section 7.6 of Book III.

--- Programming Note ---

There are many events that might cause a Load or Store instruction to be restarted. For example, a hardware error may cause execution of the instruction to be aborted after part of the access has been performed, and the recovery operation could then cause the aborted instruction to be re-executed.

When an instruction is aborted after being partially executed, the contents of the instruction pointer indicate that the instruction has not been executed, however, the contents of some registers may have been altered and some bytes within the storage operand may have been accessed. The following are examples of an instruction being partially executed and altering the program state even though it appears that the instruction has not been executed.

1. Load Multiple, Load String: Some registers in the range of registers to be loaded may have been altered.
2. Any Store instruction, dcbz: Some bytes of the storage operand may have been altered.

--- Programming Note ---

In order to ensure that the contents of registers are preserved to the extent that a partially executed instruction can be re-executed correctly, the registers that are preserved must satisfy the following conditions. For any given instruction, zero or more of the conditions applies.

- For a fixed-point Load instruction that is not a multiple or string form, if RT=RA or RT=RB then the contents of register RT are not altered.
- For an update form Load or Store instruction, the contents of register RA are not altered.
Chapter 3. Management of Shared Resources

The facilities described in this section provide the means to control the use of resources that are shared with other processors.

3.1 Program Priority Registers

The Program Priority Register (PPR) is a 64-bit register that controls the program’s priority. The PPR provides access to the full 64-bit PPR, and the Program Priority Register 32-bit (PPR32) provides access to the upper 32 bits of the PPR. The layouts of the PPR and PPR32 are shown in Figure 1.

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>11:13</td>
<td>Program Priority (PRI)</td>
</tr>
<tr>
<td>(PPR3243:45)</td>
<td></td>
</tr>
<tr>
<td>001</td>
<td>very low</td>
</tr>
<tr>
<td>010</td>
<td>low</td>
</tr>
<tr>
<td>011</td>
<td>medium low</td>
</tr>
<tr>
<td>100</td>
<td>medium</td>
</tr>
<tr>
<td>101</td>
<td>medium high</td>
</tr>
</tbody>
</table>

Programs can always set the PRI field to very low, low, medium low, and medium priorities; programs may be allowed to set the PRI field to medium high priority during certain time intervals. (See Section 5.3.6.) If the program priority is medium high when the time interval expires or if an attempt is made to set the priority to medium high when it is not allowed, the PRI field is set to medium.

If other values are written to this field, the PRI field is not changed. (See Section 5.3.5 of Book III for additional information.)

All other fields are reserved.

Programming Note

The ability to access the low-order half of the PPR (and thus the use of mfppr and mtppr) might be phased out in a future version of the architecture.

Programming Note

By setting the PRI field, a programmer may be able to improve system throughput by causing system resources to be used more efficiently.

E.g., if a program is waiting on a lock (see Section B.2), it could set low priority, with the result that more processor resources would be diverted to the program that holds the lock. This diversion of resources may enable the lock-holding program to complete the operation under the lock more quickly, and then relinquish the lock to the waiting program.

Programming Note

or Rx,Rx,Rx can be used to modify the PRI field; see Section 3.2.

Programming Note

When the system error handler is invoked, the PRI field may be set to an undefined value.

Figure 1. Program Priority Register
3.2 “or” Instruction

Setting the PPR

The or Rx,Rx,Rx (see Book I) instruction can be used to set PPRPRI as shown in Table 1. or Rx,Rx,Rx does not set PPRPRI.

<table>
<thead>
<tr>
<th>Rx</th>

</tr>
<tr>
<td>5</td>
<td>101</td>
<td>medium high</td>
</tr>
</tbody>
</table>

Table 1: Priority levels for or Rx,Rx,Rx

Programs can always set the PRI field to very low, low, medium low, and medium priorities; programs may be allowed to set the PRI field to medium high priority during certain time intervals. (See Section 5.3.6 of Book III.) If the program priority is medium high when the time interval expires or if an attempt is made to set the priority to medium high when it is not allowed, the PRI field is set to medium.

Programming Note

Warning: Other forms of or Rx,Rx,Rx that are not described in this section and in Section 4.3.3 may also cause program priority to change. Use of these forms should be avoided except when software explicitly intends to alter program priority. If a no-op is needed, the preferred no-op (ori 0,0,0) should be used.
Chapter 4.  Storage Control Instructions

4.1 Parameters Useful to Application Programs

It is suggested that the operating system provide a service that allows an application program to obtain the following information.

1. The virtual page sizes
2. Coherence block size
3. Reservation granule size
4. An indication of the cache model implemented (e.g., Harvard-style cache, combined cache)
5. Instruction cache size
6. Data cache size
7. Instruction cache block size
8. Data cache block size
9. Instruction cache associativity
10. Data cache associativity
11. Number of stream IDs supported for the stream variant of dcbt
12. Factors for converting the Time Base to seconds

If the caches are combined, the same value should be given for an instruction cache attribute and the corresponding data cache attribute.

4.2 Data Stream Control Register (DSCR)

The layout of the Data Stream Control Register (DSCR) is shown in Figure 2 below.

Figure 2.  Data Stream Control Register

</tr>
</tbody>
</table>
59  **Stride-N Stream Enable** (SNSE)
0  No effect.
1  Enables the hardware detection and initiation of load and store streams that have a stride greater than a single cache block. Such load streams are detected only when LSD is also zero. Such store streams are detected only when SSE is also one.

60  **Store Stream Enable** (SSE)
0  No effect.
1  Enables hardware detection and initiation of store streams.

61:63  **Default Prefetch Depth** (DPFD)
This field supplies a prefetch depth for hardware-detected streams and for software-defined streams for which a depth of zero is specified or for which `dcbt/dcbtst` with TH=1010 is not used in their description. Values and their meanings are as follows.
0  default (LPCR_{DPFD})
1  none
2  shallowest
3  shallow
4  medium
5  deep
6  deeper
7  deepest

The contents of the DSCR affect how a processor handles hardware-detected and software-defined data streams. The DSCR provides the only means by which software can control or supply information for hardware-detected data streams. The DPFD, UNITCNT, and transient fields may also be used instead of the TH=01010 variant of `dcbt` for software-defined data streams, especially when multiple streams have these attributes in common. See Section 4.3.2, “Data Cache Instructions” on page 1053, for information on streams and how software may specify them.

--- Programming Note ---

The purpose of Depth Attainment Urgency is to regulate the rate of prefetch generation from the cycle at which the hardware first detects an incipient stream until the cycle when the prefetch Depth is reached. A more urgent setting will benefit applications that are dominated by short to medium length streams, because otherwise prefetching does not occur rapidly enough to benefit them. In contrast, applications that frequently cause unproductive prefetches due to stream mispredictions will benefit from a less urgent setting.

Unlike the Depth, the Depth Attainment Urgency applies only to hardware-detected streams. Furthermore, the DSCR provides the only point of control for this parameter. Software-defined streams are assumed not to have the correctness risk associated with hardware streams, and therefore are set to reach their depth relatively quickly.

--- Programming Note ---

In versions of the architecture that precede Version 2.07, `mtspr` specifying the DSCR caused all active and nascent data streams to cease to exist. In those versions of the architecture, the DSCR was used as an overall control mechanism to specify a single global profile for all streams. Beginning with Version 2.07, the DSCR is intended to control and accelerate the creation of new streams without disturbing existing streams.

--- Programming Note ---

The URG, LSD, SNSE and SSE fields do not affect the initiation of streams specified using the `dcbt` and `dcbtst` instructions.

Note that even when SNSE is not set, hardware may detect Stride-N streams in intervals when they access elements that map to sequential cache blocks.

--- Programming Note ---

In order for the DSCR to apply the transient attribute to streams, at least two of the four enable bits must be set: one to choose a type of access (load or store), and one to choose a kind of prefetching (software-defined or hardware-detected).
4.3 Cache Management Instructions

The Cache Management instructions obey the sequential execution model except as described in Section 4.3.1.

In the instruction descriptions the statements “this instruction is treated as a Load” and “this instruction is treated as a Store” mean that the instruction is treated as a Load (Store) from (to) the addressed byte with respect to address translation, the definition of program order on page 1029, storage protection, reference and change recording, the storage access ordering described in Section 1.7.1, and Performance Monitor events (see Section 10.4.5 of Book III).

Some Cache Management instructions contain a CT field that is used to specify a cache level within a cache hierarchy or a portion of a cache structure to which the instruction is to be applied. The correspondence between the CT value specified and the cache level is shown below.

<table>
<thead>
<tr>
<th>CT Field Value</th>
<th>Cache Level</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Primary Cache</td>
</tr>
<tr>
<td>2</td>
<td>Secondary Cache</td>
</tr>
</tbody>
</table>

CT values not shown above may be used to specify implementation-dependent cache levels or implementation-dependent portions of a cache structure.
### 4.3.1 Instruction Cache Instructions

**Instruction Cache Block Invalidate X-form**

\[ \text{icbi RA, RB} \]

Let the effective address (EA) be the sum \((RA|0)+(RB)\).

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required and a block containing the byte addressed by EA is in the instruction cache of any processors, the block is invalidated in those instruction caches.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and the block is in the instruction cache of this processor, the block is invalidated in that instruction cache.

The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.

This instruction is treated as a Load (see Section 4.3), except that reference and change recording need not be done.

**Special Registers Altered:**

None

---

**Programming Note**

Because the instruction is treated as a Load, the effective address is translated using translation resources that are used for data accesses, even though the block being invalidated was copied into the instruction cache based on translation resources used for instruction fetches (see Book III).

---

**Programming Note**

The invalidation of the specified block need not have been performed with respect to the processor executing the icbi instruction until a subsequent isync instruction has been executed by that processor. No other instruction or event has the corresponding effect.

---

**Instruction Cache Block Touch X-form**

\[ \text{icbt CT, RA, RB} \]

Let the effective address (EA) be the sum \((RA|0)+(RB)\).

The icbt instruction provides a hint that the program will probably soon execute code from the block containing the byte addressed by EA, and that the block containing the byte addressed by EA is to be loaded into the cache specified by the CT field. (See Section 4.3 of Book II.) If the CT field is set to a value not supported by the implementation, no operation is performed.

The hint is ignored if the block is Caching Inhibited.

This instruction treated as a Load (see Section 4.3), except that the system data storage error handler is not invoked, and reference and change recording need not be done.

**Special Registers Altered:**

None
4.3.2 Data Cache Instructions

The Data Cache instructions control various aspects of the data cache.

**TH field in the dcbt and dcbtst instructions**

Described below are the TH field values for the dcbt and dcbtst instructions. For all TH field values which are not listed, the hint provided by the instruction is undefined.

**TH=0b00000**

If TH=0b00000, the dcbt/dcbtst instruction provides a hint that the program will probably soon access the block containing the byte addressed by EA.

**TH=0b01000 - 0b01111**

The dcbt/dcbtst instructions provide hints regarding a sequence of accesses to data elements, or indicate the expected use thereof. Such a sequence is called a “data stream”, and a dcbt/dcbtst instruction in which TH is set to one of these values is said to be a “data stream variant” of dcbt/dcbtst. In the remainder of this section, “data stream” may be abbreviated to “stream”.

A data stream to which a program may perform Load accesses is said to be a “load data stream”, and is described using the data stream variants of the dcbt instruction. A data stream to which a program may perform Store accesses is said to be a “store data stream”, and is described using the data stream variants of the dcbtst instruction.

When, and how often, effective addresses for a data stream are translated is implementation-dependent.

Each data element is associated with a unit of storage, which is the aligned 128-byte location in storage that contains the first byte of the element. The data stream variants may be used to specify the address of the beginning of the data stream, the displacement (stride) between the first byte of successive elements, and the number of unique units of storage that are associated with all of the data elements. If the stride is specified, both the stride and the address of the first element are specified at 4 byte granularity. If the stride is not specified, the address of the first element is the address of the first unit.

**Programming Note**

The architecture does not provide a way to specify the size of the data elements that compose a stream. An implementation may assume some fixed size for all data elements. As a result, depending on the offset, stride, and size (and in particular whether the elements are aligned), the implementation may reduce the latency for accessing only a portion of some of the elements. A future version of the architecture may enable the specification of element size to avoid this limitation.

Each such data stream is associated, by software, with a stream ID, which is a resource that the processor uses to distinguish the data stream from other such data streams. The number of stream IDs is an implementation-dependent value in the range 1:16. Stream IDs are numbered sequentially starting from 0.

**Programming Note**

The number of stream IDs available for a program to use may be dependent on the current degree of multithreading of a processor in the system.

The encodings of the TH field and of the corresponding EA values are as follows. In the EA layout diagrams, fields shown as “/”s are reserved. These reserved fields are treated in the same manner as the corresponding case for instruction fields (see Section 1.3.3 of Book I). If a reserved value is specified for a defined EA field, or if a TH value is specified that is not explicitly defined below, the hint provided by the instruction is undefined.

<table>
<thead>
<tr>
<th>TH</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0100</td>
<td>The dcbt/dcbtst instruction provides a hint that describes certain attributes of a data stream, and may indicate that the program will probably soon access the stream. The EA is interpreted as follows.</td>
</tr>
</tbody>

<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

35 Reserved

36:38 Depth (DEP)
The DEP field provides a relative estimate of how many elements ahead of the point of stream use the latency-reducing actions should go. This value reflects a comparison of the rate of consumption of the elements of the data stream and the latency to bring an arbitrary element of the stream into cache. The values are as follows.

| Depth | 0 default = DSCR$_{DPFD}$ | 1 none | 2 shallowest | 3 shallow | 4 medium | 5 deep | 6 deeper | 7 deepest |

39:46 Reserved

47:56 UNITCNT
Number of units in data stream.

57 Transient (T)
If T=1, the program’s need for each element of the data stream is likely to be transient (i.e., the time interval during which the program accesses the element is likely to be short).

58 Unlimited (U)
If U=1, the number of units in the data stream is unlimited (and the UNITCNT field is ignored).

59 Reserved

60:63 Stream ID (ID)
Stream ID to use for this data stream (GO=0 and S=0b00), or stream ID associated with the data stream which the program will probably no longer access (S=0b10).
### Programming Note

To maximize the utility of the Depth control mechanism, the architecture provides a hierarchy of three ways to program it. The DPFD field in the LPCR is used by the provisory/firmware to set a safe or appropriate default depth for unaware operating systems and applications. The DPFD field in the DSCR may be initialized by the aware OS and overwritten by an application via the OS-provided service when per stream control is unnecessary or unaffordable. The DEP field in the EA specification when TH=0b01010 may be used by the application to specify the depth on a per-stream basis.

The number of elements ahead of the point of stream use indicated by a given depth value may differ across implementations, as may the latency to bring a given element into the cache. To achieve optimum performance, some experimentation with different depth values may be necessary.

### Table: Bit(s) Description

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:31</td>

<tr>
<td>50</td>
<td>Reserved</td>
</tr>
<tr>
<td>51:55</td>
<td>Offset</td>
</tr>
<tr>
<td>60:63</td>
<td>Stream ID (ID)</td>
</tr>
</tbody>
</table>

The displacement, in words, between the first byte of successive elements in the stream. The effective address of the Nth element in the stream is

\[(N-1) \times \text{STRIDE} \times 4\]

greater than or less than the effective address of the first element of the stream, depending on the direction specified for the stream.

If the specified stream ID value is greater than m-1, where m is the number of stream IDs provided by the implementation, and either (a) TH=0b01000 or TH=0b01011, or (b) TH=0b01010 with GO=0 and S\(\neq 0b11\), no hint is provided by the instruction.

The following terminology is used to describe the state of a data stream. Except as described in the paragraph after the next paragraph, the state of a data stream at a given time is determined by the most recently provided hint(s) for the stream.

- A data stream for which only descriptive hints have been provided (by `dcbt/dcbtst` instructions with TH=0b01000 and UG=0, TH=0b01010 and GO=0 and S=0b00, and/or with TH=0b01011) is said to be "nascent". A nascent data stream for which all relevant descriptive hints have been provided (by the `dcbt/dcbtst` usages listed in the preceding sentence) is considered to be "completely described". The order of descriptive hints with respect to one another is unimportant.

- A data stream for which a hint has been provided (by a `dcbt/dcbtst` instruction with TH=0b01000 and UG=1 or `dcbt` with TH=0b01010 and GO=1) that the program will probably soon access it is said to be "active".

- A data stream that is either nascent or active is considered to "exist".

- A data stream for which a hint has been provided (e.g., by a `dcbt` instruction with TH=0b01010 and S\(\neq 0b00\)) that the program will probably no longer access it is considered no longer to exist.

The hint provided by a `dcbt/dcbtst` instruction with TH=0b01000 and UG=1 implicitly includes a hint that the program will probably no longer access the data stream (if any) previously associated with the specified stream ID. The hint provided by a `dcbt/dcbtst` instruction with TH=0b01000 and UG=0, or with TH=0b01010 and GO=0 and S=0b00, or with TH=0b01011 implicitly includes a hint that the program will probably no longer access the active data stream (if any) previously associated with the specified stream ID.

If a data stream is specified without using a `dcbt/dcbtst` instruction with TH=0b01010 and GO=0 and S=0b00, then the number of elements in the stream is unlimited, and the program's need for each element of the stream is not likely to be transient. If a data stream is specified without using a `dcbt/dcbtst` instruction with
TH=0b01011, then the stream will access consecutive units of storage.

A context switch on a particular thread causes all existing data streams for that thread to cease to exist. The mechanism of detection of a context switch is implementation-dependent. In addition, depending on the implementation, certain conditions and events may cause an existing data stream to cease to exist; for example, in some implementations an existing data stream ceases to exist when it comes to the end of a page.
Programming Note

To obtain the best performance across the widest range of implementations that support the data stream variants of `dcbt/dcbtst`, the programmer should assume the following model when using those variants.

- The processor's response to a hint that the program will probably soon access a given data stream is to take actions that reduce the latency of accesses to the first few elements of the stream. (Such actions may include prefetching cache blocks into levels of the storage hierarchy that are "near" the processor.) Thereafter, as the program accesses each successive element of the stream, the processor takes latency-reducing actions for additional elements of the stream, pacing these actions with the program's accesses (i.e., taking the actions for only a limited number of elements ahead of the element that the program is currently accessing).

- The processor's response to a hint that the program will probably no longer access a given data stream, or to the cessation of existence of a data stream, is to stop taking latency-reducing actions for the stream.

- A data stream having finite length ceases to exist when the latency-reducing actions have been taken for all elements of the stream.

- If the program ceases to need a given data stream before having accessed all elements of the stream (always the case for streams having unlimited length), performance may be improved if the program then provides a hint that it will no longer access the stream (e.g., by executing the appropriate `dcbt` instruction with TH=0b01010 and S≠0b00).

- At each level of the storage hierarchy that is "near" the processor, elements of a data stream that is specified as transient are most likely to be replaced. As a result, it may be desirable to stagger addresses of streams (choose addresses that map to different cache congruence classes) to reduce the likelihood that an element of a transient stream will be replaced prior to being accessed by the program.

- Processors that comply with versions of the architecture that do not support the TH field at all treat TH = 0b01000, 0b01010, and 0b01011 as if TH = 0b00000.

- A single set of stream IDs is shared between the `dcbt` and `dcbtst` instructions.

- On some implementations, data streams that are not specified by software may be detected by the processor. Such data streams are called "hardware-detected data streams". On some such implementations, data stream resources (resources that are used primarily to support data streams) are shared between software-specified data streams and hardware-detected data streams. On these latter implementations, the programming model includes the following.
  - Software-specified data streams take precedence over hardware-detected data streams in use of data stream resources.
  - The processor's response to a hint that the program will probably no longer access a given data stream, or to the cessation of existence of a data stream, includes releasing the associated data stream resources, so that they can be used by hardware-detected data streams.
The latency-reducing actions taken in response to a program’s hints about access to a data stream, including the depth and urgency parameters, may vary based on its behavior and on the behavior of other programs sharing platform resources, as well as on the design of the platform resources they use. Without actually changing the stream specification or DSCR parameters, the processor may adjust its actions (e.g. slow down prefetches or be more selective choosing them) based on their effectiveness and on the availability of storage bandwidth. In general, the goal of this variation is to improve overall system performance and fairness across the set of programs that share resources. There often will be a performance benefit, however, from adjusting stream specifications to the platform and co-resident programs to adjust for these actions by the processor.
This Programming Note describes several aspects of using the data stream variants of the `dcbt` and `dcbtst` instructions.

- A non-transient data stream having unlimited length and which will access consecutive units in storage can be completely specified, including providing the hint that the program will probably soon access it, using one `dcbt` instruction. The corresponding specification for a data stream having other attributes requires two or three `dcbt/dcbtst` instructions to describe the stream and one additional `dcbt` instruction to start the stream. However, one `dcbt` instruction with TH=0b01010 and GO=1 can apply to a set of the data streams described in the preceding sentence, so the corresponding specification for n such data streams requires 2×n to 3×n `dcbt/dcbtst` instructions plus one `dcbt` instruction. (There is no need to execute a `dcbt/dcbtst` instruction with TH=0b01010 and S=0b10 for a given stream ID before using the stream ID for a new data stream; the implicit portion of the hint provided by `dcbt/dcbtst` instructions that describe data streams suffices.)

- If it is desired that the hint provided by a given `dcbt/dcbtst` instruction be provided in program order with respect to the hint provided by another `dcbt/dcbtst` instruction, the two instructions must be separated by an `eieio` instruction. For example, if a `dcbt` instruction with TH=0b01010 and GO=1 is intended to indicate that the program will probably soon access nascent data streams described (completely) by preceding `dcbt/dcbtst` instructions, and is intended not to indicate that the program will probably soon access nascent data streams described (completely) by following `dcbt/dcbtst` instructions, an `eieio` instruction must separate the `dcbt` instruction with GO=1 from the preceding `dcbt/dcbtst` instructions, and another `eieio` instruction must separate that `dcbt` instruction from the following `dcbt/dcbtst` instructions.

- In practice, the second `eieio` described above can sometimes be omitted. For example, if the program consists of an outer loop that contains the `dcbt/dcbtst` instructions and an inner loop that contains the `Load` or `Store` instructions that access the data streams, the characteristics of the inner loop and of the implementation's branch prediction mechanisms may make it highly unlikely that hints corresponding to a given iteration of the outer loop will be provided out of program order with respect to hints corresponding to the previous iteration of the outer loop. (Also, any providing of hints out of program order affects only performance, not program correctness.)

- To mitigate the effects of context switches on data streams, it may be desirable to specify a given "logical" data stream as a sequence of shorter, component data streams. Similar considerations apply to conditions and events that, depending on the implementation, may cause an existing data stream to cease to exist; for example, in some implementations an existing data stream ceases to exist when it comes to the end of a virtual page.

- If it is desired to specify data streams without regard to the number of stream IDs provided by the implementation, stream IDs should be assigned to data streams in order of decreasing stream importance (stream ID 0 to the most important stream, stream ID 1 to the next most important stream, etc.). This order ensures that the hints for the most important data streams will be provided.

- In practice, it is usually the case that it is preferable for data streams of the main or parent application running on a particular thread to be prioritized over data streams of a leaf or child application or function call. As an example, a library function call would usually fall under the category of a leaf function whose data streams should be treated with lower priority than those of the parent. As such, it is advised that programmers writing library functions or other functions which are expected to have leaf routing use the lowest stream priority possible. For example, if a leaf-type function instantiates two data streams, best practice is to use stream ID 14 for its most important data stream, and stream ID 15 for its second most important stream.

**Version 3.1**

**Chapter 4. Storage Control Instructions**

---

**TH=0b10000**

If TH=0b10000, the `dcbt` instruction provides a hint that the program will probably soon load from the block containing the byte addressed by EA, and that the program’s need for the block will be transient (i.e., the time interval during which the program accesses the block is likely to be short).
TH=0b10001

If TH=0b10001, the $dcbt$ instruction provides a hint that the program will probably not access the block containing the byte addressed by EA for a relatively long period of time.
**Data Cache Block Touch X-form**

\[ \text{dcbt RA,RB,TH} \]

Let the effective address (EA) be the sum \((RA|0)+(RB)\).

The `dcbt` instruction provides a hint that describes a block or data stream to which the program may perform a Load access. The instruction is also used to indicate imminent access or end of access to described load and store data streams. A hint that the program will probably soon load from a given storage location is ignored if the location is Caching Inhibited or Guarded.

The only operation that is “caused” by the `dcbt` instruction is the providing of the hint. The actions (if any) taken by the processor in response to the hint are not considered to be “caused by” or “associated with” the `dcbt` instruction (e.g., `dcbt` is considered not to cause any data accesses). No means are provided by which software can synchronize these actions with the execution of the instruction stream. For example, these actions are not ordered by memory barriers.

The `dcbt` instruction may complete before the operation it causes has been performed.

The nature of the hint depends, in part, on the value of the TH field, as specified at the beginning of this section. If \(TH\neq 0b01010\) and \(TH\neq 0b01011\), this instruction is treated as a Load (see Section 4.3), except that the system data storage error handler is not invoked, and reference and change recording need not be done.

**Special Registers Altered:**

None

**Extended Mnemonics:**

Extended mnemonics are provided for the `Data Cache Block Touch` instruction so that it can be coded with the TH value as the last operand for all categories, and so that the transient hint can be specified without coding the TH field explicitly.

**Extended:**

- `dcbct RA,RB,TH`
- `dcbtds RA,RB,TH`
- `dcbtt RA,RB`
- `dcbna RA,RB`

**Equivalent to:**

- `dcbt for TH values of 0b00000 - 0b00111`
- `dcbt for TH values of 0b00000 or 0b01000 - 0b01111`
- `dcbt for TH value of 0b10000`
- `dcbt for TH value of 0b10000`

New programs should avoid using the `dcbt` and `dcbtst` mnemonics; one of the extended mnemonics should be used exclusively.

If the `dcbt` mnemonic is used with only two operands, the TH operand is assumed to be 0b00000.

Processors that comply with versions of the architecture that precede Version 2.01 do not necessarily ignore the hint provided by `dcbt` and `dcbtst` if the specified block is in storage that is Guarded and not Caching Inhibited.

See the Programming Notes at the beginning of this section.
**Data Cache Block Touch for Store X-form**

```
dcbtst RA,RB,TH
```

Let the effective address (EA) be the sum (RA|0)+(RB).

The `dcbtst` instruction provides a hint that describes a block or data stream to which the program may perform a Store access, or indicates the expected use thereof. A hint that the program will soon store to a given storage location is ignored if the location is Caching Inhibited or Guarded.

The only operation that is “caused by” the `dcbtst` instruction is the providing of the hint. The actions (if any) taken by the processor in response to the hint are not considered to be “caused by” or “associated with” the `dcbtst` instruction (e.g., `dcbtst` is considered not to cause any data accesses). No means are provided by which software can synchronize these actions with the execution of the instruction stream. For example, these actions are not ordered by memory barriers.

The `dcbtst` instruction may complete before the operation it causes has been performed.

The nature of the hint depends, in part, on the value of the TH field, as specified at the beginning of this section. If TH=0b00000 or TH=0b01000, this instruction is treated as a `Store` (see Section 4.3), except that the system data storage error handler is not invoked, reference recording need not be done, and change recording is not done.

**Special Registers Altered:**

None

**Extended Mnemonics:**

Extended mnemonics are provided for the `Data Cache Block Touch for Store` instruction so that it can be coded with the TH value as the last operand for all categories, and so that the transient hint can be specified without coding the TH field explicitly.

**Extended:**

<table>
<thead>
<tr>
<th>Extended</th>

<td>dcbtst for TH value of 0b10000.</td>
</tr>
</tbody>
</table>

**Programming Note**

See the Programming Notes at the beginning of this section.
**Data Cache Block set to Zero X-form**

\[ \text{dcbz \ RA, RB} \]

\[
\begin{array}{cccccc}
0 & 31 & // & 8 & 11 & 16 & 21 & 1014 & / 31
\end{array}
\]

if RA = 0 then \( b \leftarrow 0 \)
else \( b \leftarrow (RA) \)
\( EA \leftarrow b + (RB) \)
\( n \leftarrow \text{block size (bytes)} \)
\( m \leftarrow \log_2(n) \)
\( ea \leftarrow E_{0:63-m} \| n_0 \)
\( \text{MEM}(ea, n) \leftarrow 0x00 \)

Let the effective address (EA) be the sum (RA\(0\)+RB).

All bytes in the block containing the byte addressed by EA are set to zero.

This instruction is treated as a Store (see Section 4.3).

**Special Registers Altered:**
- None

**Programming Note**

\[ \text{dcbz} \] does not cause the block to exist in the data cache if the block is in storage that is Caching Inhibited.

For storage that is neither Write Through Required nor Caching Inhibited, \text{dcbz} provides an efficient means of setting blocks of storage to zero. It can be used to initialize large areas of such storage, in a manner that is likely to consume less memory bandwidth than an equivalent sequence of Store instructions.

For storage that is either Write Through Required or Caching Inhibited, \text{dcbz} is likely to take significantly longer to execute than an equivalent sequence of Store instructions. For example, on some implementations dcbz for such storage may cause the system alignment error handler to be invoked; on such implementations the system alignment error handler sets the specified block to zero using Store instructions.

See Section 6.9.1 of Book III for additional information about \text{dcbz}.

---

**Data Cache Block Store X-form**

\[ \text{dcbst \ RA, RB} \]

\[
\begin{array}{cccccc}
0 & 31 & // & 8 & 11 & 16 & 21 & 54 & / 31
\end{array}
\]

Let the effective address (EA) be the sum (RA\(0\)+RB).

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required and a block containing the byte addressed by EA is in the data cache of any processor and any locations in the block are considered to be modified there, those locations are written to main storage, additional locations in the block may be written to main storage, and the block ceases to be considered to be modified in that data cache.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and the block is in the data cache of this processor and any locations in the block are considered to be modified there, those locations are written to main storage, additional locations in the block may be written to main storage, and the block ceases to be considered to be modified in that data cache.

The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.

This instruction is treated as a Load (see Section 4.3), except that reference and change recording need not be done.

**Special Registers Altered:**
- None

**Programming Note**

\[ \text{Data Cache Block Store to Persistent Storage} \] is encoded as a variant of \text{Data Cache Block Flush}. This was necessary so that the instruction has the correct behavior on processors that implement Version 3.0C. The extended mnemonic (\text{dcbstps}) indicates the intended function. (There is expected to be no interest in attaching persistent storage to processors that comply with versions of the architecture that precede Version 3.0C.)
Data Cache Block Flush X-form

dcbf RA, RB, L

Let the effective address (EA) be the sum (RA|0)+(RB).

L=0

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required and a block containing the byte addressed by EA is in the data cache of any processor and any locations in the block are considered to be modified there, those locations are written to main storage and additional locations in the block may be written to main storage. The block is invalidated in the data caches of all processors.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and the block is in the data cache of this processor and any locations in the block are considered to be modified there, those locations are written to main storage and additional locations in the block may be written to main storage. The block is invalidated in the data cache of this processor.

L=1 (“dcbf local”)

The L=1 form of the dcbf instruction permits a program to limit the scope of the “flush” operation to the data cache of this processor. If the block containing the byte addressed by EA is in the data cache of this processor, it is removed from this cache. The coherence of the block is maintained to the extent required by the Memory Coherence Required storage attribute.

L = 3 (“dcbf local primary”)

The L=3 form of the dcbf instruction permits a program to limit the scope of the “flush” operation to the primary data cache of this processor. If the block containing the byte addressed by EA is in the primary data cache of this processor, it is removed from this cache. The coherence of the block is maintained to the extent required by the Memory Coherence Required storage attribute.

L = 4 (“data cache block flush to persistent storage”)

The L=4 form of the dcbf instruction performs all of the functions of dcbf with L=0. After all writes to main storage, caused by these functions, have updated main storage, if the block maps to main storage that is backed by persistent storage then all locations in the block in main storage that are considered to be modified relative to persistent storage are written to persistent storage and additional locations in the block in main storage may be written to persistent storage.

L = 6 (“data cache block store to persistent storage”)

The L=6 form of the dcbf instruction performs all of the functions of dcbst. After all writes to main storage, caused by these functions, have updated main storage, if the block maps to main storage that is backed by persistent storage then all locations in the block in main storage that are considered to be modified relative to persistent storage are written to persistent storage and additional locations in the block in main storage may be written to persistent storage.

Programming Note

This form of the dcbf instruction is considered to be a functional extension of dcbst, and its extended mnemonic reflects that association.

For the L operand, the values 2, 5, and 7 are reserved. The results of executing a dcbf instruction with L=2, 5, or 7 are boundedly undefined.

The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.

This instruction is treated as a Load (see Section 4.3), except that reference and change recording need not be done.

Special Registers Altered:

None

Extended Mnemonics:

Extended mnemonics are provided for the Data Cache Block Flush instruction so that it can be coded with the L value as part of the mnemonic rather than as a numeric operand. These are shown as examples with the instruction. See Appendix A. “Assembler Extended Mnemonics” on page 1105. The extended mnemonics are shown below.

<table>
<thead>
<tr>
<th>Extended:</th>
<th>Equivalent to:</th>
</tr>
</thead>
<tbody>
<tr>
<td>dcbf RA, RB</td>
<td>dcbf RA, RB, 0</td>
</tr>
<tr>
<td>dcbfl RA, RB</td>
<td>dcbf RA, RB, 1</td>
</tr>
<tr>
<td>dcbflp RA, RB</td>
<td>dcbf RA, RB, 3</td>
</tr>
<tr>
<td>dcbfps RA, RB</td>
<td>dcbf RA, RB, 4</td>
</tr>
<tr>
<td>dcbstps RA, RB</td>
<td>dcbf RA, RB, 6</td>
</tr>
</tbody>
</table>

Except in the dcbf instruction description in this section, references to “dcbf” in Books I-III imply L=0 unless otherwise stated or obvious from context; “dcbfl” is used for L=1, “dcbflp” is used for L=3, “dcbfps” is used for L=4, and “dcbstps” is used for L=6.
4.3.2.1 Obsolete Data Cache Instructions

The Data Stream Touch (dst), Data Stream Touch for Store (dstt), and Data Stream Stop (dss) instructions (primary opcode 31, extended opcodes 342, 374, and 822 respectively), which were proposed for addition to the Power ISA and were implemented by some processors, must be treated as no-ops (rather than as illegal instructions).

The treatment of these instructions is independent of whether other Vector instructions are available (i.e., is independent of the contents of MSRVEC (see Book III).

Programming Note

These instructions merely provided hints, and thus were permitted to be treated as no-ops even on processors that implemented them.

The treatment of these instructions is independent of whether other Vector instructions are available because, on processors that implemented the instructions, the instructions were available even when other Vector instructions were not.

The extended mnemonics for these instructions were dstt, dsttt, and dssall.
4.3.3 “or” Instruction

“or” Cache Control Hint

This form of or provides a hint that stores caused by preceding Store and dcbz instructions should be performed with respect to other processors and mechanisms as soon as is feasible.

Extended Mnemonics:

Additional extended mnemonic for the or hint:

<table>
<thead>
<tr>
<th>Extended</th>
<th>Equivalent to:</th>
</tr>
</thead>
<tbody>
<tr>
<td>miso</td>
<td>or 26,26,26</td>
</tr>
</tbody>
</table>

“miso” is short for “make it so.”

Programming Note

Warning: Other forms of or Rx,Rx,Rx that are not described in this section and in Section 3.2 may also cause program priority to change. Use of these forms should be avoided except when software explicitly intends to alter program priority. If a no-op is needed, the preferred no-op (ori 0,0,0) should be used.

Extended: Equivalent to:
miso or 26,26,26

This form of the or instruction can be used to reduce latency in producer-consumer applications by requesting that modified data be made visible to other processors quickly. In this example it is assumed that the base register is GPR3.

Producer:

```
addi r1,r0,0x1234
sth r1,0x1000(r3) # store data value 0x1234
lwsync # order store before flag store
addi r2,r0,0x0001
sth r2,0x1002(r3) # store nonzero flag byte
or r26,r26,r26 # miso
p_loop:
  lbz r2,0x1002(r3) # load flag byte
  andi r2,r2,0x00FF
  bne p_loop # wait for consumer to clear flag
```

Consumer:

```
c_loop:
  lbz r2,0x1002(r3) # load flag byte
  andi r2,r2,0x00FF
  beq c_loop # wait for producer to set flag to nonzero
  lwsync # order load before data load
  lhz r1,0x1000(r3) # load data value
  lwsync # order load before flag store
  addi r2,r0,0x0000
  stb r2,0x1002(r3) # clear flag byte
  or r26,r26,r26 # miso
```
4.4 Copy-Paste Facility

The Copy-Paste Facility provides a means to copy a block of data from one storage location to another. The most straightforward application is memcpy. Depending on the platform configuration, other alternatives such as posting a work element to an accelerator’s queue or copying a block to another system may be supported. The facility uses pairs of instructions, copy followed by paste, to define the data transfers. (See Section 1.7.1.1, “Storage Ordering of Copy/Paste-Initiated Data Transfers” for the memory model characteristics of these data transfers.)

The requirements for use of the platform-specific functionality may vary across implementations. The specific details are beyond the scope of the Architecture. Authority to use an accelerator is generally established through a call to the hypervisor. The format of the work element is accelerator-specific. Mappings for transfers between systems are generally managed by the operating system. Each transfer preserves the order of bytes in storage and is not affected by the endian mode of the processor.

Since the buffer that holds the block until a data transfer is performed is hidden state (cannot be saved and restored) and there is no way to save the state of the copy, any disruption of program execution (e.g. interrupts, event-based branch) has the potential to prevent the data transfer from completing correctly. The software that handles the disruption is responsible for executing cpabort to clear the state associated with an outstanding data transfer if it will use the Copy-Paste Facility itself or transfer control to another program that might use the facility prior to returning control to the original program.

Correct use of the Copy-Paste Facility consists of a series of copy/paste pairs. The two instructions in a pair need not be adjacent in the instruction stream. Two or more copy instructions with no intervening paste produces a “copy-paste sequence error.” Similarly, a bare paste, with no preceding copy, produces a copy-paste sequence error. Copy-paste sequence errors are reported by the paste for the malformed sequence of instructions.

Programming Note

A paste instruction is ordered with respect to its preceding copy by a dependency on the copy buffer. No explicit synchronization or barrier is required.

Programming Note

WARNING: In rare circumstances, paste, may falsely report successful completion when the copy-paste sequence is coded incorrectly. This may occur if the instruction sequence includes a redundant copy and the sequence is interrupted just prior to the redundant copy. Since interrupts should be rare, any sequence that returns a false positive CR0 value should fail for most executions.

Programming Note

It is always best to avoid unnecessary instructions between the copy and the paste.

Successful transfers are indicated when paste returns 0b001x in CR0. Transient errors (a copy-paste sequence error, a memory management state change (tlbi[fl]) during the transfer, or an implementation-specific transient problem) are indicated by a CR0 value of 0b000x, indicating the sequence should be retried. A sequence error is considered transient because it could have been caused by an interruption between the copy and paste.) Fatal errors unique to the Copy-Paste Facility (attempting to copy from an accelerator or attempting to use an accelerator that has not been properly configured) cause the system data storage error handler to be invoked when the (associated) paste instruction is executed. paste instructions that cause or report transient errors, fatal errors unique to the Copy-Paste Facility, or successful transfer completion reset the state of the facility so that a subsequent copy-paste sequence can begin with a clean slate.

Programming Note

For paste, to address space mapped to another system, OS control over that mapping is deemed to be a sufficient check on the configuration of the channel to the other system, so that a unique data storage interrupt type is not required.
The Copy-Paste Facility is the only means to address an accelerator. If any other storage access (implicit or explicit, instruction or data) addresses an accelerator, a Machine Check exception will result. Unlike other Machine Check exceptions, this one will generally be presented with ordering and priority similar to that for a storage protection exception.

### Copy X-form

copy RA,RB

```
0 31 10 16 21 31
31 6 9 10 11 16 21
```

if RA = 0 then b ← 0
else
   b ← (RA)

EA ← b + (RB)

copy_buffer ← memory(EA,128) || MEMmetadata(EA,128)

Let the effective address (EA) be the sum (RA|0)+(RB).

The 128 bytes in storage, and associated metadata, addressed by EA is loaded into the copy buffer.

If the EA is not a multiple of 128, the system alignment error handler is invoked.

If the specified block is in storage that is Caching Inhibited, the system data storage error handler is invoked.

When successful, this instruction is treated as a Load (see Section 4.3, "Cache Management Instructions"), except that the data transfer ordering is described in Section 1.7.1.1, "Storage Ordering of Copy/Paste-Initiated Data Transfers".

### Paste X-form

paste. RA,RB,L

```
0 31 6 9 10 11 16 21 31
31 6 9 10 11 16 21
```

if there was a copy-paste sequence error or a translation conflict
   CR0 ← 0b000 || XER_S0
else
   if RA = 0 then b ← 0
   else
      b ← (RA)
   EA ← b + (RB)
   if L=1 then
      copy_buffer.md ← 0 /* clear metadata in buffer
   wait for completion status
   if there was a data transfer problem
      CR0 ← 0b000 || XER_S0
   else
      CR0 ← 0b001 || XER_S0
   clear the state of the Copy-Paste Facility

If there was a copy-paste sequence error or a translation conflict, set CR0 to indicate failure. Otherwise, continue as follows.

Let the effective address (EA) be the sum (RA|0)+(RB).

If L=1, then set metadata bits in the copy buffer to zero.

The physical target of the operation, and by implication the function to be performed, is determined by the real address that is translated from EA. If the real address is in the platform’s system memory, a simple copy is performed. If the real address has an associated mapping to another system, the copy buffer is transmitted to the other system. If the real address is control memory for an accelerator, the contents of the copy buffer is queued to the accelerator. There is a wait for completion status on the data transfer. CR0 is set as follows based on the completion status.

<table>
<thead>
<tr>
<th>CR0</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0b000</td>
<td></td>
</tr>
<tr>
<td>0b001</td>
<td></td>
</tr>
</tbody>
</table>

The state of the Copy-Paste Facility is cleared.

If MSR_PP=1, paste. with L=0 is an invalid form.

If the EA is not a multiple of 128, the system alignment error handler is invoked.

If the specified block is in storage that is Caching Inhibited, the system data storage error handler is invoked.

### Programming Note

A failure of a data transfer may be the result of a shortage of the resources required to complete the operation. (Such failures should only take place for accelerator invocations,) When the resources are known to be shared by multiple programs, a credit-based system is frequently used to improve quality of service. If such a credit system is in use, or if the resources are not shared, the program should continually repeat the copy/paste, pair until it succeeds. However, if no credit system is in use for shared resources, it may be appropriate to apply some sort of backoff algorithm after having retried the copy/paste, pair a few times.

### Programming Note

Accelerator address space is to be marked No-execute by the hypervisor, so that an instruction fetch will violate storage protection rather than causing a Machine Check.

### Special Registers Altered:

None
If the associated copy specified an accelerator or the paste. specifies an accelerator that was not properly configured, the data storage error handler will be invoked.

When successful, this instruction is treated as a Store (see Section 4.3, “Cache Management Instructions”), except that the data transfer ordering is described in Section 1.7.1.1, “Storage Ordering of Copy/Paste-Initiated Data Transfers”.

Special Registers Altered:

CR0

Extended Mnemonics:

Extended mnemonic for paste.:

<table>
<thead>
<tr>
<th>Extended:</th>
<th>Equivalent to:</th>
</tr>
</thead>
<tbody>
<tr>
<td>paste. RA, RB</td>
<td>paste. RA, RB, 1</td>
</tr>
</tbody>
</table>

**Copy-Paste Abort X-form**

cpabort

```
0 31 8 11 16 21 838 31
```

clear the state of the Copy-Paste Facility

The *cpabort* instruction causes a data transfer to fail if one is in progress.

Any pending errors in the Copy-Paste Facility are cleared and the state is reset to prepare for a new *copy*.

**Special Registers Altered:**

None
4.5 Atomic Memory Operations

The Atomic Memory Operation (AMO) facility may be used to optimize performance when many software threads are manipulating shared control structures concurrently. In such situations, accessing the shared data frequently involves transferring the data from one processor’s cache to another. The latency of such transfers can become the limiting factor in the performance of some environments. Rather than moving the data to the work, AMOs move the work to the data. The mental model is of an agent consisting of an execution unit and a work queue near memory that receives atomic update requests from all the processors in the system.

Despite that AMOs are performed at memory, their function is only defined for storage that is not Caching Inhibited. This is done so that software can transparently access the same data using normal loads and stores. But furthermore, AMOs generally behave as typical explicit storage accesses performed by the thread, with respect to storage access ordering. The few complications are described below. Since the performance advantage of AMOs derives from avoiding time of flight through cache hierarchies, software should avoid frequent mixing of normal loads and stores to the same storage locations. AMOs are also restricted to storage that is not Guarded and storage that is not Write Through Required to limit implementation complexity.

The facility specifies a set of atomic update operations that a processor may send, accompanied by operands from GPRs, to the memory to be performed. The operations are expressed using the Load Atomic (LAT) and Store Atomic (STAT) instructions. Each of these instructions performs an atomic update operation (load followed by some manipulation and a store) on some location in storage. As a result, these instructions are considered to be both fixed-point Load instructions and fixed-point Store instructions, and any reference elsewhere in the architecture to fixed-point Load or fixed-point Store instructions apply to these instructions as well, unless otherwise stated or obvious from context. For example, in order to perform an AMO, it is necessary to have both read and write access to the storage location. Another example is that the DAWR will detect a match if either Data Read or Data Write is selected. Yet another example is that a Trace interrupt will indicate both a Load and a Store instruction have been executed. Barrier action will be based on whether the barrier would give a load or a store the stronger ordering. The difference between the Load Atomic instructions and the Store Atomic instructions is simply that the Load Atomic instructions return a result to a GPR, while the Store Atomic instructions do not. In the RTL in the following subsections, the “lat” and “stat” functions represent the manipulations performed by the memory agent. The parameters shown are the maximum storage footprint, the maximum list of registers, and the function code that are provided to the agent. If the specified registers wrap (e.g. RT=R31 and RT+1=R0), the wrapping is permitted. Such an instruction is not an invalid form. Destructive encodings are also permitted (i.e. a LAT specified with RT=RA).

Except in this section, references to “atomic update” in Books I-III imply use of the Load And Reserve and Store Conditional instructions unless otherwise stated or obvious from context.

--- Programming Note

The best performance for the Atomic Memory Operations will be realized when the targeted storage locations are accessed only using AMOs. If it is necessary to perform other i=0 loads and stores to those addresses, the result will still be correct, but performance will suffer. In such circumstances, it is not helpful to performance to flush the data to memory using dcbf.

--- Programming Note

Note that the descriptions of AMO operations are Endian independent. The only effect of Endian on these operations is the obvious one that byte significance within an individual datum reflects the Endian mode.

4.5.1 Load Atomic

The Atomic Loads perform an atomic update to an aligned memory location and return a value to a GPR. The manipulation performed on the memory value and the value that is returned in the GPR are determined by the function code (FC) specified by the instruction. The name of each function and its associated RTL are shown in Figure 3.

- Function codes not listed in this table are considered invalid.
- For word atomics, only the least significant word of each source register is used.

Figure 4. Store Atomic function codes
Store Word Atomic X-form

stwat RS,RA,FC

if RA=0 then EA ← 0
else EA ← (RA)
mem(EA,8) ← stat(mem(EA,8), RS32:63, FC)

Let the effective address (EA) be (RA). Four or eight bytes of storage at EA are updated as specified by store atomic function code FC. Input operands are function code specific, and may include RS32:63 and mem(EA,8).

Figure 4 contains the valid function codes. An attempt to execute stwat specifying an invalid function code will cause the system data storage error handler to be invoked.

EA must be a multiple of 4, and the portion of mem(EA,8) accessed by the instruction must be contained within an aligned 32-byte block of storage. If either of these requirements is not satisfied, the system alignment error handler is invoked.

Special Registers Altered:
None

Store Doubleword Atomic X-form

stdat RS,RA,FC

if RA=0 then EA ← 0
else EA ← (RA)
mem(EA,16) ← stat(mem(EA,16), RS, FC)

Let the effective address (EA) be (RA). Eight or sixteen bytes of storage at EA are updated as specified by store atomic function code FC. Input operands are function code specific, and may include RS and mem(EA,16).

Figure 4 contains the valid function codes. An attempt to execute stdat specifying an invalid function code will cause the system data storage error handler to be invoked.

EA must be a multiple of 8, and the portion of mem(EA,16) accessed by the instruction must be contained within an aligned 32-byte block of storage. If either of these requirements is not satisfied, the system alignment error handler is invoked.

Special Registers Altered:
None
4.6 Synchronization Instructions

The synchronization instructions are used to ensure that certain instructions have completed before other instructions are initiated, or to control storage access ordering, or to support debug operations.

4.6.1 Instruction Synchronize Instruction

**Instruction Synchronize XL-form**

isync

Executing an *isync* instruction ensures that all instructions preceding the *isync* instruction have completed before the *isync* instruction completes, and that no subsequent instructions are initiated until after the *isync* instruction completes. It also ensures that all instruction cache block invalidations caused by *icbi* instructions preceding the *isync* instruction have been performed with respect to the processor executing the *isync* instruction, and then causes any prefetched instructions to be discarded.

Except as described in the preceding sentence, the *isync* instruction may complete before storage accesses associated with instructions preceding the *isync* instruction have been performed.

This instruction is context synchronizing (see Book III).

**Special Registers Altered:**

None

4.6.2 Load And Reserve and Store Conditional Instructions

The *Load And Reserve and Store Conditional* instructions can be used to construct a sequence of instructions that appears to perform an atomic update operation on an aligned storage location. See Section 1.7.2, “Atomic Update” for additional information about these instructions.

The *Load And Reserve and Store Conditional* instructions are fixed-point *Storage Access* instructions; see Section 3.3.1, “Fixed-Point Storage Access Instructions”, in Book I.

The storage location specified by the *Load And Reserve* and *Store Conditional* instructions must be in storage that is Memory Coherence Required if the location may be modified by another processor or mechanism. If the specified location is in storage that is Write Through Required or Caching Inhibited, the system data storage error handler is invoked.

The *Load And Reserve* instructions include an Exclusive Access hint (EH), which can be used to indicate that the instruction sequence being executed is implementing one of two types of algorithms:

**Atomic Update (EH=0)**

This hint indicates that the program is using a fetch and operate (e.g., fetch and add) or some similar algorithm and that all programs accessing the shared variable are likely to use a similar operation to access the shared variable for some time.

**Exclusive Access (EH=1)**

This hint indicates that the program is attempting to acquire a lock and if it succeeds, will perform another store to the lock variable (releasing the lock) before another program attempts to modify the lock variable.

**Programming Note**

The Memory Coherence Required attribute on other processors and mechanisms ensures that their stores to the reservation granule will cause the reservation created by the *Load And Reserve* instruction to be lost.
**Programming Note**

Because the Load And Reserve and Store Conditional instructions have implementation dependencies (e.g., the granularity at which reservations are managed), they must be used with care. The operating system should provide system library programs that use these instructions to implement the high-level synchronization functions (Test and Set, Compare and Swap, locking, etc.; see Appendix B) that are needed by application programs. Application programs should use these library programs, rather than use the Load And Reserve and Store Conditional instructions directly.

**Programming Note**

EH = 1 should be used when the program is obtaining a lock variable which it will subsequently release before another program attempts to perform a store to it. When contention for a lock is significant, using this hint may reduce the number of times a cache block is transferred between processor caches.

EH = 0 should be used when all accesses to a mutex variable are performed using an instruction sequence with Load And Reserve followed by Store Conditional (e.g., emulating atomic update primitives such as "Fetch and Add;" see Appendix B). The processor may use this hint to optimize the cache to cache transfer of the block containing the mutex variable, thus reducing the latency of performing an operation such as 'Fetch and Add'.

**Programming Note**

Warning: On some processors that comply with versions of the architecture that precede Version 2.00, executing a Load And Reserve instruction in which EH = 1 will cause the illegal instruction error handler to be invoked.

---

**Load Byte And Reserve Indexed X-form**

\[
\text{lbarx RT,RA,RB,EH} \\
\begin{array}{cccccc}
31 & 28 & 24 & 20 & 16 & 12 \\
\text{RT} & \text{RA} & \text{RB} & \text{EA} & \text{EH} \\
0 & 6 & 11 & 16 & 21 & 31
\end{array}
\]

\[
\begin{align*}
\text{if RA} &= 0 \ \text{then b} \leftarrow 0 \\
\text{else} & \quad \text{b} \leftarrow (RA) \\
\text{EA} & \leftarrow (RA)+(RB) \\
\text{RESERVE} & \leftarrow 1 \\
\text{RESERVE\_LENGTH} & \leftarrow 1 \\
\text{RESERVE\_ADDR} & \leftarrow \text{real\_addr}(EA) \\
\text{RT} & \leftarrow 56:63 \ | | \ \text{MEM}(EA, 1)
\end{align*}
\]

Let the effective address (EA) be the sum (RA|0)+(RB).

This instruction creates a reservation for use by a stbcx or waitrsv instruction. A real address computed from the EA as described in Section 1.7.2.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 1 byte is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the byte in storage addressed by EA before some other processor attempts to modify it.

0 Other programs might attempt to modify the byte in storage addressed by EA regardless of the result of the corresponding stbcx instruction.

1 Other programs will not attempt to modify the byte in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

**Special Registers Altered:**

None

---

**Programming Note**

lbarx serves as both a basic and an extended mnemonic. The Assembler will recognize a lbarx mnemonic with four operands as the basic form, and a lbarx mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.
Load Halfword And Reserve Indexed X-form

**lharx RT,RA,RB,EH**

| 31 | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |

else b ← (RA)

EA ← b +(RB)
RESERVE ← 1
RESERVE_LENGTH ← 2
RESERVE_ADDR ← real_addr(EA)
RT ← 160 || MEM(EA, 2)

Let the effective address (EA) be the sum (RA|0)+(RB).
The halfword in storage addressed by EA is loaded into RT48:63. RT0:47 are set to 0.

This instruction creates a reservation for use by a sthcx. or waitrsv instruction. A real address computed from the EA as described in Section 1.7.2.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 2 bytes is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the halfword in storage addressed by EA before some other processor attempts to modify it.

0 Other programs might attempt to modify the halfword in storage addressed by EA regardless of the result of the corresponding sthcx. instruction.
1 Other programs will not attempt to modify the halfword in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

EA must be a multiple of 2. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

**Special Registers Altered:**
None

**Programming Note**

*lharx* serves as both a basic and an extended mnemonic. The Assembler will recognize a *lharx* mnemonic with four operands as the basic form, and a *lharx* mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

Load Word And Reserve Indexed X-form

**lwarx RT,RA,RB,EH**

| 31 | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|-----|
| 0  | 6  | 11 | 16 | 21 | 31 |

if RA = 0 then b ← 0
else b ← (RA)

EA ← b +(RB)
RESERVE ← 1
RESERVE_LENGTH ← 4
RESERVE_ADDR ← real_addr(EA)
RT ← 160 || MEM(EA, 4)

Let the effective address (EA) be the sum (RA|0)+(RB).
The word in storage addressed by EA is loaded into RT32:63. RT0:31 are set to 0.

This instruction creates a reservation for use by a stwcx. or waitrsv instruction. A real address computed from the EA as described in Section 1.7.2.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 4 bytes is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the word in storage addressed by EA before some other processor attempts to modify it.

0 Other programs might attempt to modify the word in storage addressed by EA regardless of the result of the corresponding stwcx. instruction.
1 Other programs will not attempt to modify the word in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

EA must be a multiple of 4. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

**Special Registers Altered:**
None

**Programming Note**

*lwarx* serves as both a basic and an extended mnemonic. The Assembler will recognize a *lwarx* mnemonic with four operands as the basic form, and a *lwarx* mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

  u2 ← undefined 1-bit value
  CR0 ← 0b00 || u2 || XERSO
else
  CR0 ← 0b00 || store_performed || XERSO
RESERVE ← 0

Let the effective address (EA) be the sum (RA|0)+(RB).

If a reservation exists, the length associated with the reservation is 1 byte, and the real storage location specified by the **stbcx**. is the same as the real storage location specified by the **lbarx** instruction that established the reservation, (RS)56:63 are stored into the byte in storage addressed by EA.

If a reservation exists, and either the length associated with the reservation is not 1 byte or the real storage location specified by the **stbcx**. is not the same as the real storage location specified by the **lbarx** instruction that established the reservation, the following applies. Let z denote the smallest real page size supported by the implementation. If the real storage location specified by the **stbcx**. is in the same aligned z-byte block of real storage as the real storage location specified by the **lbarx** instruction that established the reservation, it is undefined whether (RS)56:63 are stored into the byte in storage addressed by EA. Otherwise, no store is performed.

If a reservation does not exist, no store is performed.

CR Field 0 is set as follows. n is a 1-bit value that indicates whether the store was performed, except that if, per the preceding description, it is undefined whether the store is performed, the value of n is undefined (and need not reflect whether the store was performed).

\[ CR0_{LT \; GT \; EQ \; SO} = 0b00 || n || XERSO \]

The reservation is cleared.

**Special Registers Altered:**

RESERVE ← 0

Let the effective address (EA) be the sum (RA|0)+(RB).

If a reservation exists, the length associated with the reservation is 2 bytes, and the real storage location specified by the **sthcx.** is the same as the real storage location specified by the **lharx** instruction that established the reservation, (RS)48:63 are stored into the halfword in storage addressed by EA.

If a reservation exists, and either the length associated with the reservation is not 2 bytes or the real storage location specified by the **sthcx.** is not the same as the real storage location specified by the **lharx** instruction that established the reservation, the following applies. Let z denote the smallest real page size supported by the implementation. If the real storage location specified by the **sthcx.** is in the same aligned z-byte block of real storage as the real storage location specified by the **lharx** instruction that established the reservation, it is undefined whether (RS)48:63 are stored into the halfword in storage addressed by EA. Otherwise, no store is performed.

If a reservation does not exist, no store is performed.

CR Field 0 is set as follows. n is a 1-bit value that indicates whether the store was performed, except that if, per the preceding description, it is undefined whether the store is performed, the value of n is undefined (and need not reflect whether the store was performed).

\[ CR_0LT_GT_EQ_S0 = 0b00 \ || \ n \ || XERSO \]

The reservation is cleared.

EA must be a multiple of 2. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

4.6.3 Memory Barrier Instructions

The Memory Barrier instructions can be used to control the order in which storage accesses and data transfers are performed. Additional information about these instructions and about related aspects of storage management can be found in Book III.

**Synchronize X-form**

<table>
<thead>
<tr>
<th></th>
<th>L</th>
<th>SC</th>
</tr>
</thead>
<tbody>
<tr>
<td>sync</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

if SC¹0 then switch(SC)
  case(1): stncisync
  case(2): stcisync
  case(3): stsync
else switch(L)
  case(0): hwsync
  case(1): lwsync
  case(2): ptesync
  case(4): phwsync
  case(5): plwsync

The *sync* instruction creates a memory barrier (see Section 1.7.1). The set of storage accesses and/or data transfers that is ordered by the memory barrier depends on the contents of the L and SC fields as follows.

- **SC=0**
  - L=0 ("heavyweight sync")
    The memory barrier provides an ordering function for the storage accesses and data transfers associated with all instructions that are executed by the processor executing the *sync* instruction with the exception of *dcbfps* and *dcbstps*. The applicable pairs are all pairs $a_i, b_j$ of such storage accesses and data transfers in which $b_j$ is a data access or data transfer, except that if $a_i$ is the storage access caused by an *icbi* instruction then $b_j$ may be performed with respect to the processor executing the *sync* instruction before $a_i$ is performed with respect to that processor.
  - L=1 ("lightweight sync")
    The memory barrier provides an ordering function for the storage accesses caused by *Load*, *Store*, and *dcbz* instructions that are executed by the processor executing the *sync* instruction and for which the specified storage location is in storage that is Memory Coherence Required and is neither Write Through Required nor Caching Inhibited. The applicable pairs are all pairs $a_i, b_j$ of such storage accesses except those in which $a_i$ is a storage access caused by a *Store* or *dcbz* instruction and $b_j$ is an access caused by a *Load* instruction.
  - L=2 ("ptesync")
    The set of storage accesses that is ordered by the memory barrier is described in Section 6.9.2 of Book III, as are additional properties of the *sync* instruction with L=2.
  - L=4 ("persistent heavyweight sync")
    The ordering done by the memory barrier is the same as for *sync* with L=0, but extended by adding accesses caused by *dcbfps* and *dcbstps* to both the set A and the set B of the barrier. In addition, the memory barrier ensures that all stores for which the modifications are written to persistent storage by preceding *dcbfps* and *dcbstps* instructions have updated persistent storage before any data access or data transfer caused by subsequent instructions is initiated.
  - L=5 ("persistent lightweight sync")
    The ordering done by the memory barrier is the same as for *sync* with L=1, but extended by adding accesses caused by *dcbfps* and *dcbstps* to both the set A and the set B of the barrier. In addition, the memory barrier ensures that all stores for which the modified...
tions are written to persistent storage by preceding \texttt{dcbfps} and \texttt{dcbstps} instructions have updated persistent storage before any store in set B updates persistent storage.

The ordering done by the memory barrier is cumulative (regardless of the L and SC values).

If L=0 or L=4 (or L=2), the \texttt{sync} instruction has the following additional properties.

- Executing the \texttt{sync} instruction ensures that all instructions preceding the \texttt{sync} instruction have completed before the \texttt{sync} instruction completes, and that no subsequent instructions are initiated until after the \texttt{sync} instruction completes.

- The \texttt{sync} instruction is execution synchronizing (see Book III). However, address translation and reference and change recording (see Book III) associated with subsequent instructions may be performed before the \texttt{sync} instruction completes.

- The memory barrier provides the additional ordering function such that if a given instruction that is the result of a store in set B is executed, all applicable storage accesses in set A have been performed with respect to the processor executing the instruction to the extent required by the associated memory coherence properties. The single exception is that any storage access in set A that is caused by an \texttt{icbi} instruction executed by the processor executing the \texttt{sync} instruction (P1) may not have been performed with respect to P1 (see the description of the \texttt{icbi} instruction on page 1052).

The cumulative properties of the memory barrier apply to the execution of the given instruction as they would to a load that returned a value that was the result of a store in set B.

\begin{center}
\textbf{Programming Note}
\end{center}

Section 1.8 contains a detailed description of how to modify instructions such that a well-defined result is obtained.

The L values 3, 6, and 7 are reserved.

The \texttt{sync} instruction may complete before storage accesses associated with instructions preceding the \texttt{sync} instruction have been performed.

Figure 5 shows the valid combinations of SC and L values. Instructions that use any of these combinations will execute correctly on processors that comply with versions of the architecture that precede Version 3.1 (in which versions the L field is two bits long, the SC field does not exist, and bits 8 and 14:15 of the \texttt{sync} instruction are reserved) and on processors that comply with Version 3.1 and subsequent versions of the architecture. If any other combination is used, the instruction form is invalid.

\begin{center}

Except in the \texttt{sync} instruction description in this section, references to "\texttt{sync}" in Books I-III imply L=0.

\begin{center}
\textbf{Chapter 4. Storage Control Instructions 1087}
\end{center}
unless otherwise stated or obvious from context; the appropriate extended mnemonics are used when other L values are intended. Throughout Books I-III, references to the L field imply SC=0 unless otherwise stated or obvious from context. The SC field is mentioned explicitly, or the appropriate extended mnemonics are used, when non-zero SC values are intended. Some programming examples and recommendations assume a programming model that does not include the store-specific variants of \texttt{sync}. Improved performance may be achieved through the use of store-specific memory barriers in some cases.

---

**Programming Note**

\texttt{sync} serves as both a basic and an extended mnemonic. The Assembler will recognize a \texttt{sync} mnemonic with two operands as the basic form, and a \texttt{sync} mnemonic with one operand or with no operand as an extended form. In the extended form with one operand the SC operand is omitted and assumed to be 0. In the extended form with no operand the L and SC operands are omitted and assumed to be 0.

---

**Programming Note**

The \texttt{sync} instruction can be used to ensure that all stores into a data structure, caused by \texttt{Store} instructions executed in a “critical section” of a program, will be performed with respect to another processor before the store that releases the lock is performed with respect to that processor; see Section B.2, “Lock Acquisition and Release, and Related Techniques” on page 1109.

The memory barrier created by a \texttt{sync} instruction with L=1 (or with SC=0) does not order implicit storage accesses or instruction fetches. The memory barrier created by a \texttt{sync} instruction with L=0 (or L=2) orders implicit storage accesses and instruction fetches associated with instructions preceding the \texttt{sync} instruction but not those associated with instructions following the \texttt{sync} instruction.

In order to obtain the best performance across the widest range of implementations, the programmer should use the \texttt{sync} instruction with L=1 or with SC=0, or the \texttt{eieio} instruction, if any of these is sufficient for his needs; otherwise he should use \texttt{sync} with L=0 (or with L=4 or L=5 if he needs to order accesses to persistent storage). \texttt{sync} with L=2 should not be used by application programs.

---

**Programming Note**

The functions provided by \texttt{sync} with L=1 and with SC=0 are a strict subset of those provided by \texttt{sync} with L=0. (The functions provided by \texttt{sync} with L=2 are a strict superset of those provided by \texttt{sync} with L=4; see Book III.)

---

**Enforce In-order Execution of I/O X-form**

\texttt{eieio}

\begin{tabular}{|c|c|c|c|c|c|}
\hline
31 & 30 & 29 & 28 & 27 & 854\
\hline
\end{tabular}

The \texttt{eieio} instruction creates a memory barrier (see Section 1.7.1, “Storage Access Ordering”), which provides an ordering function for the storage accesses caused by \texttt{Load}, \texttt{Store}, and \texttt{dcbz} instructions executed by the processor executing the \texttt{eieio} instruction. These storage accesses are divided into the two sets listed below. The storage access caused by a \texttt{dcbz} instruction is ordered as a store.

1. Loads and stores to storage that is both Caching Inhibited and Guarded, and stores to main storage caused by stores to storage that is Write Through Required.

   The applicable pairs are all pairs $a_i, b_j$ of such accesses.

2. Stores to storage that is Memory Coherence Required and is neither Write Through Required nor Caching Inhibited.

   The applicable pairs are all pairs $a_i, b_j$ of such accesses.

The operations caused by the stream variants of the \texttt{dcbt} and \texttt{dcbtst} instructions (i.e., the providing of hints) are ordered by \texttt{eieio} as a third set of operations, the operations caused by \texttt{tlbie} and \texttt{tlbsync} instructions (see Book III) are ordered by \texttt{eieio} as a fourth set of operations, and the operations caused by \texttt{slbieg} or \texttt{slbias} and \texttt{slbsync} instructions (see Book III) are ordered by \texttt{eieio} as a fifth set of operations.

Each of the five sets of storage accesses or operations is ordered independently of the other four sets. The ordering done by \texttt{eieio}'s memory barrier for the second set is cumulative; the ordering done by \texttt{eieio}'s memory barrier for the other four sets is not cumulative.

The \texttt{eieio} instruction may complete before storage accesses associated with instructions preceding the \texttt{eieio} instruction have been performed. The \texttt{eieio} instruction may complete before operations caused by \texttt{dcbt} and \texttt{dcbtst} instructions preceding the \texttt{eieio} instruction have been performed.

**Special Registers Altered:**

None
The **eieio** instruction is intended for use in doing memory-mapped I/O. Because loads, and separately stores, to storage that is both Caching Inhibited and Guarded are performed in program order (see Section 1.7.1, “Storage Access Ordering” on page 1034), **eieio** is needed for such storage only when loads must be ordered with respect to stores.

For the **eieio** instruction, accesses in set 1, \(a_i\) and \(b_j\) need not be the same kind of access or be to storage having the same storage control attributes. For example, \(a_i\) can be a load to Caching Inhibited, Guarded storage, and \(b_j\) a store to Write Through Required storage.

If stronger ordering is desired than that provided by **eieio**, the **sync** instruction must be used, with the appropriate value in the L field.

---

**Programming Note**

The functions provided by **eieio** for its second set are a strict subset of those provided by **sync** with \(L=1\).
4.6.4 Wait Instruction

The wait instruction is used to stop instruction fetching and execution until certain events occur. These events include exceptions (see Section 1.2.1 of Book III), event-based branch exceptions (see Section 1.1), the passage of a specified amount of time, and the modification of a storage location.

**Wait X-form**

```
wait WC,PL
```

The `wait` instruction causes instruction fetching and execution to be suspended under certain conditions, depending on the values of the WC and PL fields. Instruction fetching and execution are resumed when the events specified by the WC field occur or in the rare case of an implementation-dependent event.

The values of the WC field are as follows.

<table>
<thead>
<tr>
<th>WC</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Resume instruction fetching and execution when an exception or event-based branch exception occurs.</td>
</tr>
<tr>
<td>1</td>
<td>Resume instruction fetching and execution when an exception or event-based branch exception occurs, or when a reservation made by the processor does not exist (see Section 1.7.2.1).</td>
</tr>
<tr>
<td>2</td>
<td>Resume instruction fetching and execution when an exception or event-based branch exception occurs, or when the amount of time specified by the PL field has passed.</td>
</tr>
<tr>
<td>3</td>
<td>Reserved.</td>
</tr>
</tbody>
</table>

The values of the PL field are as follows.

<table>
<thead>
<tr>
<th>PL</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>00</td>
<td>A short wait time is specified.</td>
</tr>
<tr>
<td>11</td>
<td>Reserved.</td>
</tr>
</tbody>
</table>

If WC=0, or if WC=1 and a reservation made by the processor exists, or if WC=2 and a value for PL that is not reserved is specified, the following applies.

- Upon completion of the instruction, instruction fetching and execution is suspended.
- Instruction fetching and execution resumes when any of the following conditions are met.
  - An exception or event-based branch exception occurs.
  - WC=1 and a reservation made by the processor does not exist.
  - WC=2 and the specified amount of time has passed.
  - An implementation-dependent event occurs.

---

**Programming Note**

Because the waiting begins when the instruction completes, if the waiting is ended by an exception that causes a change of control flow (interrupt, event-based branch), the SPR that is set to reflect the point in the instruction stream at which the change of control flow occurred (e.g., SRR0 for a Decrementer interrupt) will contain the EA of the instruction following the wait instruction.

If WC=1 and a reservation made by the processor does not exist, or if WC=2 and a reserved value of PL is specified, the instruction is treated as a no-op.

**Programming Note**

Bits 6 and 7 of the `wait` instruction may be used in some implementations for an implementation-dependent field. Unless the intention is to use the implementation-dependent field, these bits must be coded zero.

**Special Registers Altered:**

None

**Extended Mnemonics:**

Examples of extended mnemonics for `wait`:

<table>
<thead>
<tr>
<th>Extended</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td>wait</td>
<td>wait 0,0</td>
</tr>
<tr>
<td>wait 0</td>
<td>wait 0,0</td>
</tr>
<tr>
<td>wait 1</td>
<td>wait 1,0</td>
</tr>
<tr>
<td>waitcsv</td>
<td>wait 1,0</td>
</tr>
<tr>
<td>pause_short</td>
<td>wait 2,0</td>
</tr>
</tbody>
</table>

Except in this section, references to “`wait`” in Books I-III include all defined forms of `wait` unless otherwise stated or obvious from context.

**Programming Note**

`wait` serves as both a basic and an extended mnemonic. The Assembler will recognize a `wait` mnemonic with two operands as the basic form and a `wait` mnemonic with one operand or with no operand as an extended form. In the extended form with one operand the PL operand is omitted and assumed to be 0. In the extended form with no operand the WC and PL operands are omitted and assumed to be 0.
The `wait` instruction frees computational resources which might be allocated to another program or converted into power savings.

Since exceptions corresponding to system-caused interrupts (see Section 7.4 of Book III) may occur at any time, including immediately prior to the `wait` instruction, applications should not depend on them to cause `wait` to resume. In order to ensure timely resumption, therefore, applications should execute `wait` only in order to suspend processing until an event-based branch exception or loss of reservation occurs or a specified amount of time has passed.

Also, since exceptions corresponding to interrupts can cause `wait` to resume at any time without any EBB exception or loss of reservation having occurred, and in consideration of the possibility of resuming because of an implementation-dependent event, programs that execute `wait` should check that the expected condition has actually occurred after the `wait` instruction completes. If the expected condition has not occurred, `wait` should be re-executed. An example code usage is shown below.

```c
while (!expected_condition), wait
```

Applications that execute `wait` in order to suspend processing until an external event-based branch exception occurs (see Section 6.2) should enable external event-based branch exceptions (by setting BESCREE=1) and disable event-based branches (by setting BESCRGE=0) before executing `wait`. If BESCRGE=1, then the expected event-based branch exception may cause the corresponding event-based branch to occur immediately prior to execution of the `wait` instruction. This will result in a hang condition since the EBB exception that was expected to cause `wait` to resume will have already occurred.
Chapter 5. Time Base

The Time Base (TB) is a 64-bit register (see Figure 6) containing a 64-bit unsigned integer that is incremented periodically as described below.

<table>
<thead>
<tr>
<th>Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>TBU</td>
<td>Upper 32 bits of Time Base</td>
</tr>
<tr>
<td>TBL</td>
<td>Lower 32 bits of Time Base</td>
</tr>
</tbody>
</table>

Figure 6. Time Base

The Time Base monotonically increments until its value becomes \( 0xFFFF_FFFF_FFFF_FFFF \) (\( 2^{64} - 1 \)); at the next increment its value becomes \( 0x0000_0000_0000_0000 \). There is no interrupt or other indication when this occurs.

The suggested frequency at which the time base increments is 512 MHz, however, variation from this rate is allowed provided the following requirements are met.

- The contents of the Time Base differ by no more than \( +/- \) four counts from what they would be if they incremented at the required frequency.
- Bit 63 of the Time Base is set to 1 between 30% and 70% of the time over any time interval of at least 16 counts.

The Power ISA does not specify a relationship between the frequency at which the Time Base is updated and other frequencies, such as the CPU clock or bus clock. The Time Base update frequency is not required to be constant. What is required, so that system software can keep time of day and operate interval timers, is one of the following.

- The system provides an (implementation-dependent) interrupt to software whenever the update frequency of the Time Base changes, and a means to determine what the current update frequency is.
- The update frequency of the Time Base is under the control of the system software.

Programming Note

If the operating system initializes the Time Base on power-on to some reasonable value and the update frequency of the Time Base is constant, the Time Base can be used as a source of values that increase at a constant rate, such as for time stamps in trace entries.

Even if the update frequency is not constant, values read from the Time Base are monotonically increasing (except when the Time Base wraps from \( 2^{64} - 1 \) to 0). If a trace entry is recorded each time the update frequency changes, the sequence of Time Base values can be post-processed to become actual time values.

Successive readings of the Time Base may return identical values.
5.1 Time Base Instructions

**Move From Time Base XFX-form**

mftb RT, TBR

[Phased-Out]

This instruction behaves as if it were an mfspr instruction; see the mfspr instruction description in Section 3.3.18 of Book I.

**Special Registers Altered:**

None

**Extended Mnemonics:**

Extended mnemonics for Move From Time Base:

<table>
<thead>
<tr>
<th>Extended:</th>
<th>Equivalent to:</th>
</tr>
</thead>
<tbody>
<tr>
<td>mftb Rx</td>
<td>mftb Rx, 268</td>
</tr>
<tr>
<td></td>
<td>mfspr Rx, 268</td>
</tr>
<tr>
<td>mftbu Rx</td>
<td>mftbRx, 269</td>
</tr>
<tr>
<td></td>
<td>mfsprRx, 269</td>
</tr>
</tbody>
</table>

**Programming Note**

New programs should use mfspr instead of mftb to access the Time Base.

**Programming Note**

mftb serves as both a basic and an extended mnemonic. The Assembler will recognize an mftb mnemonic with two operands as the basic form, and an mftb mnemonic with one operand as the extended form. In the extended form the TBR operand is omitted and assumed to be 268 (the value that corresponds to TB).
Programming Note

Since the update frequency of the Time Base is implementation-dependent, the algorithm for converting the current value in the Time Base to time of day is also implementation-dependent.

As an example, assume that the Time Base increments at the constant rate of 512 MHz. (Note, however, that programs should allow for the possibility that some implementations may not increment the least-significant 4 bits of the Time Base at a constant rate.) What is wanted is the pair of 32-bit values comprising a POSIX standard clock: the number of whole seconds that have passed since 00:00:00 January 1, 1970, UTC, and the remaining fraction of a second expressed as a number of nanoseconds.

Assume that:

- The value 0 in the Time Base represents the start time of the POSIX clock (if this is not true, a simple 64-bit subtraction will make it so).
- The integer constant \( \text{ticks}_{\text{per sec}} \) contains the value 512,000,000, which is the number of times the Time Base is updated each second.
- The integer constant \( \text{ns}_{\text{adj}} \) contains the value \( \frac{1,000,000,000}{512,000,000} \times 2^{32}/2 = 4194304000 \)
  which is the number of nanoseconds per tick of the Time Base, multiplied by \( 2^{32} \) for use in \( \text{mulhwu} \) (see below), and then divided by 2 in order to fit, as an unsigned integer, into 32 bits.

When the processor is in 64-bit mode, The POSIX clock can be computed with an instruction sequence such as this:

```assembly
mfspr Ry,268  # Ry = Time Base
lwz Rx,\text{ticks}_{\text{per sec}}
divdu Rz,Ry,Rx  # Rz = whole seconds
stw Rz,\text{posix sec}
mulld Rz,Rz,Rx  # Rz = quotient * divisor
sub Rz,Ry,Rz  # Rz = excess ticks
lwz Rx,\text{ns}_{\text{adj}}
slw1 Rz,Rz,1  # Rz = 2 * excess ticks
mulhwu Rz,Rz,Rx  # mul by (ns/tick)/2 * 2^{32}
stw Rz,\text{posix ns}# product[0:31] = excess ns
```

Non-constant update frequency

In a system in which the update frequency of the Time Base may change over time, it is not possible to convert an isolated Time Base value into time of day. Instead, a Time Base value has meaning only with respect to the current update frequency and the time of day that the update frequency was last changed. Each time the update frequency changes, either the system software is notified of the change via an interrupt (see Book III), or the change was instigated by the system software itself. At each such change, the system software must compute the current time of day using the old update frequency, compute a new value of \( \text{ticks}_{\text{per sec}} \) for the new frequency, and save the time of day, Time Base value, and tick rate. Subsequent calls to compute Time of Day use the current Time Base Value and the saved value.

---

Chapter 6. Event-Based Branch Facility

6.1 Event-Based Branch Overview

The Event-Based Branch facility allows application programs to enable hardware to change the effective address of the next instruction to be executed when certain events occur to an effective address specified by the program.

The operation of the Event-Based Branch facility is summarized as follows:

- The Event-Based Branch facility is available only when the system software has made it available. See Section 10.5 of Book III for additional information.
- When the Event-Based Branch facility is available, event-based branches are caused by event-based exceptions. Event-based exceptions can be enabled to occur by setting bits in the BESCR.
- When an event-based exception occurs, the bit in the BESCR control field corresponding to the event-based exception is set to 0 and the bit in the Event Status field in the BESCR corresponding to the event-based exception is set to 1.
- If the global enable bit in the BESCR is set to 1 when any of the bits in the status field are set to 1 (i.e., when an event-based exception exists), an event-based branch occurs.
- The event-based branch causes the following to occur.
  - The global enable bit is set to 0.
  - Bits 0:61 of the EBBRR are set to the effective address of the instruction that would have attempted to execute next if the event-based branch did not occur.
  - Instruction fetch and execution continues at the effective address contained in the EBBHR.
- The event-based branch handler performs the necessary processing in response to the event, and then executes an `rfebb` instruction in order to resume execution at the instruction at the address indicated in the EBBRR.

Additional information about the Event-Based Branch facility is given in Section 4.4 of Book III.

6.2 Event-Based Branch Registers

6.2.1 Branch Event Status and Control Register

The Branch Event Status and Control Register (BESCR) is a 64-bit register that contains control and status information about the Event-Based Branch facility.
System software controls whether or not event-based branches occur regardless of the contents of the BESCR. See Section 10.4.4 of Book III and Section 7.2.13 of Book III.

The entire BESCR can be read or written using SPR 806. Individual bits of the BESCR can be set or reset using two sets of additional SPR numbers.

- When `mtspr` indicates SPR 800 (Branch Event Status and Control Set, or BESCRS), the bits in BESCR which correspond to "1" bits in the source register are set to 1; all other bits in the BESCR are unaffected. SPR 801 (BESCRSU) provides the same capability to each of the upper 32 bits of the BESCR.

- When `mtspr` indicates SPR 802 (Branch Event Status and Control Reset, or BESCRR), the bits in BESCR which correspond to "1" bits in the source register are set to 0; all other bits in the BESCR are unaffected. SPR 803 (BESCRRU) provides the same capability to each of the upper 32 bits of the BESCR.

When `mfspr` indicates any of the above SPR numbers, the current value of the register is returned.

### Programming Note

Event-based branch handlers typically reset event status bits upon entry, and enable event enable bits after processing an event. Execution of `rfebb` then re-enables the GE bit so that additional event-based branches can occur.

</tbody>
</table>
63 Performance Monitor Event-Based Exception Occurred (PMEO)
0 A Performance Monitor event-based exception has not occurred since the last time software set this bit to 0.
1 A Performance Monitor event-based exception has occurred since the last time software set this bit to 0.

This bit is set to 1 by the hardware when a Performance Monitor event-based exception occurs. This bit can be set to 0 only by the mtspr instruction.

See Chapter 10 of Book III for information about Performance Monitor event-based exceptions and about the effects of this bit on the Performance Monitor.

--- Programming Note ---
As part of processing an External EBB exception, it may also be necessary to perform additional operations to manage the external EBB input from the system. See the system documentation for details.

6.2.2 Event-Based Branch Handler Register

The Event-Based Branch Handler Register (EBBHR) is a 64-bit register that contains the 62 most significant bits of the effective address of the instruction that is executed next after an event-based branch occurs. Bits 62:63 must be available to be read and written by software.

--- Programming Note ---
After handling an event-based branch, software should set the "exception occurred" bit(s) corresponding to the event-based exception(s) that have occurred to 0. See the Programming Notes in Section 6.3 for additional information.

6.2.3 Event-Based Branch Return Register

The Event-Based Branch Return Register (EBBRR) is a 64-bit register that contains the 62 most significant bits of an instruction effective address as specified below.

```
0 Effective Address
62 63
```

--- Figure 9. Event-Based Branch Handler Register (EBBHR) ---

--- Figure 10. Event-Based Branch Return Register (EBBRR) ---

When an event-based branch occurs, bits 0:61 of the EBBRR are set to the effective address of the instruction that would have attempted to execute next if the event-based branch did not occur.

Bits 62:63 are reserved.
6.3 Event-Based Branch Instructions

Return from Event-Based Branch XL-form

rfebb S

<table>

</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>19</td>
<td>///</td>
<td>///</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

BESCRGE ← S
NIA ← EBBR0:61 || 0b00

BESCRGE is set to S.

If there are no pending event-based exceptions, then the next instruction is fetched from the address EBBR0:61 || 0b00 (when MSR SF=1) or 320 || EBBR32:61 || 0b00 (when MSR SF=0). If one or more pending event-based exceptions exist, an event-based branch is generated; in this case the value placed into EBBR by the Event-Based Branch facility is the address of the instruction that would have been executed next had the event-based branch not occurred.

If BESCR32:33 ≠ 0b00 the instruction is treated as if the instruction form were invalid.

See Section 4.4 of Book III for additional information about this instruction.

Special Registers Altered:

BESCR
MSR (See Book III)

Extended Mnemonics:

<table>
<thead>
<tr>
<th>Extended:</th>
<th>Equivalent to:</th>
</tr>
</thead>
<tbody>
<tr>
<td>rfebb</td>
<td>rfebb 1</td>
</tr>
</tbody>
</table>

**Programming Note**

*rfebb* serves as both a basic and an extended mnemonic. The Assembler will recognize an *rfebb* mnemonic with one operand as the basic form, and an *rfebb* mnemonic with no operand as the extended form. In the extended form, the S operand is omitted and assumed to be 1.

---

**Programming Note**

When an event-based branch occurs, the event-based branch handler can execute the following sequence of operations. This sequence of operations assumes that the handler routine has access to a stack or other area in memory in which state information from the main program can be stored. Note also that in this example, the handler entry point is labeled “E,” r1 and r2 are used as scratch registers, and both external EBB and Performance Monitor EBB exceptions are enabled.

E: Save state
- // This is the entry point
- mfspr r1, BESCR // Check event status
- if r163=1, then
  - Process PM exception
  - r2 ← 0x0000 0000 0000 0001
  - mtspr BESCR, r2 // Reset PMEO status bit
  - r2 ← 0x0000 0001 0000 0000
  - mtspr BESCRS, r1 // Re-enable PM exceptions
  // Note: The PMAE bit of MMCR0 must also be enabled. See Book III.
- if r162=1, then
  - Process external exception
  - r2 ← 0x0000 0000 0000 0002
  - mtspr BESCR, r2 // Reset EEO status bit
  - r2 ← 0x0000 0002 0000 0000
  // De-activate external EBB input from platform
  - mtspr BESCRS, r1 // Re-enable external EBB exceptions
  // . . .
  // Other exceptions
  // are processed similarly.
  // . . .
  - Restore state
  - rfebb 1 // return & global enable

Note that before resetting the BESCR_EEO, the external EBB input from the platform should be deactivated, and additional operations to manage the external EBB input may be required. See the system documentation for details.

In the above sequence, if other exceptions occur after they are enabled, another event-based branch will occur immediately after *rfebb* is executed.
Chapter 7. Branch History Rolling Buffer

The Branch History Rolling Buffer (BHRB) is a buffer containing an implementation-dependent number of entries, referred to as BHRB Entries (BHRBEs), that contain information related to branches that have been taken. Entries are numbered from 0 through n, where n is implementation-dependent but no more than 1023. Entry 0 is the most-recently written entry. The BHRB is read by means of the `mfbhrbe` instruction.

System software typically controls the availability of the BHRB as well as the number of entries that it contains. If the BHRB is accessed when it is unavailable, the system facility unavailable error handler is invoked.

Various events or actions by the system software may result in the BHRB occasionally being cleared. If BHRB entries are read after this has occurred, 0s will be returned. See the description of the `mfbhrbe` instruction for additional information.

The BHRB is typically used in conjunction with Performance Monitor event-based branches. (See Chapter 6 of Book II.) When used in conjunction with this facility, BESCR_PME is set to 1 to enable Performance Monitor event-based exceptions, and Performance Monitor alerts are enabled to enable the writing of BHRB entries. When a Performance Monitor alert occurs, Performance Monitor alerts are disabled, BHRB entries are no longer written, and an event-based branch occurs. (See Chapter 10 of Book III for additional information on the Performance Monitor.) The event-based branch handler can then access the contents of the BHRB for analysis.

When the BHRB is written by hardware, only those `Branch` instructions that meet the filtering criteria are written. See Section 10.4.7 of Book III.

The following paragraphs describe the entries written into the BHRB for various types of `Branch` instructions for which the branch was taken. In some circumstances, however, the hardware may be unable to make the entry even though the following paragraphs require it. In such cases, the hardware sets the EA field to 0, and indicates any missed entries using the T and P fields. (See Section 7.1.)

When an I-form or B-form `Branch` instruction is entered into the BHRB, bits 0:61 of the effective address of the `Branch` instruction are written into the next available entry, except that the entry may or may not be written in the following cases.

- The effective address of the branch target exceeds the effective address of the `Branch` instruction by 4.
- The instruction is a B-form `Branch`, the effective address of the branch target exceeds the effective address of the `Branch` instruction by 8, and the instruction immediately following the `Branch` instruction is not another `Branch` instruction.

The determination of whether the effective address of the branch target exceeds the effective address of the `Branch` instruction by 4 or 8 is made modulo $2^{64}$.

Programming Note

The cases described above, for which the BHRBE need not be written, are cases for which some implementations may optimize the execution of the `Branch` instruction (first case) or of the `Branch` instruction and the following instruction (second case) in a manner that makes writing the BHRBE difficult. Such implementations may provide a means by which system software can disable these optimizations, thereby ensuring that the corresponding BHRBEs are written normally.

When an XL-form `Branch` instruction is entered into the BHRB, bits 0:61 of the effective address of the `Branch` instruction are written into the next available entry if allowed by the filtering mode; subsequently, bits 0:61 of the effective address of the branch target are written into the following entry.
7.1 Branch History Rolling Buffer Entry Format

Branch History Rolling Buffer Entries (BHRBEs) have the following format.

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>00</td>
<td>This entry either is not implemented or has been cleared. There are no valid entries beyond the current entry.</td>
</tr>
<tr>
<td>01-11</td>
<td>Reserved.</td>
</tr>
</tbody>
</table>

When the EA field contains a zero value, bits 62:63 specify the type of marker as described below.

**Effective Address (EA)**

- When this field is set to a non-zero value, it contains bits 0:61 of the effective address of the instruction indicated by the T field; otherwise this field indicates that the entry is a marker with the meaning specified by the T and P fields.

**Target Address (T)**

- The EA field contains bits 0:61 of the effective address of a Branch instruction for which the branch was taken.
- The EA field contains bits 0:61 of the branch effective address of the branch target of an XL-form Branch instruction for which the branch was taken.

**Prediction (P)**

- When T=0, this field has the following meaning.
  - 0 The outcome of the Branch instruction was correctly predicted.
  - 1 The outcome of the Branch instruction was mispredicted.
- When T=1, this field has the following meaning.
  - 0 The Branch instruction was predicted to be taken and the target address was predicted correctly, or the target address was not predicted because the branch was predicted to be not taken.
  - 1 The target address was mispredicted.

**Programming Note**

It is expected that programs will not contain Branch instructions with instruction or target effective address equal to 0. If such instructions exist, programs cannot distinguish between entries that are markers and entries that correspond to instructions with instruction or target effective address 0.
7.2 Branch History Rolling Buffer Instructions

The Branch History Rolling Buffer instructions enable application programs to clear and read the BHRB. The availability of these instructions is controlled by the system software. (See Chapter 10 of Book III.) When an attempt is made to execute these instructions when they are unavailable, the system facility unavailable error handler is invoked.

Clear BHRB X-form

cirbhrb

for n = 0 to (number_of_BHRBES implemented - 1)
   BHRB(n) ← 0

All BHRB entries are set to 0s.

Special Registers Altered:
   None.

Move From Branch History Rolling Buffer Entry XFX-form

mfbhrbe RT,BHRBE

n ← BHRBE[0:9]
If n < number of BHRBES implemented then
   RT ← BHRBE(n)
else
   RT ← 640

The BHRBE field denotes an entry in the BHRB. If the designated entry is within the range of BHRB entries implemented and Performance Monitor alters are disable (see Section 10.5 of Book III), the contents of the designated BHRB entry are placed into register RT; otherwise, 640s are placed into register RT.

In order to ensure that the current BHRB contents are read by this instruction, one of the following must have occurred prior to this instruction and after all previous Branch and cirbhrb instructions have completed.
   ■ an event-based branch has occurred
   ■ an rfebb (see Chapter 6 of Book II) has been executed
   ■ a context synchronizing event (see Section 1.5 of Book III) other than isync (see Section 4.6.1 of Book II) has occurred.

Special Registers Altered:
   None

---

### Programming Note

In order to read all the BHRB entries containing information about taken branches, software should read the entries starting from entry number 0 and continuing until an entry containing all 0s is read or until all implemented BHRB entries have been read.

Since the number of BHRB entries may decrease or the BHRB may be cleared at any time, if a given entry, m, is read as not containing all 0s and is read again subsequently, the subsequent read may return all 0s even though the program has not executed cirbhrb.
Appendix A. Assembler Extended Mnemonics

In order to make assembler language programs simpler to write and easier to understand, a set of extended mnemonics and symbols is provided for certain instructions. This appendix defines extended mnemonics and symbols related to instructions defined in Book II. Assemblers should provide the extended mnemonics and symbols listed here, and may provide others.

A.1 Data Cache Block Touch [for Store] Mnemonics

The TH field in the Data Cache Block Touch and Data Cache Block Touch for Store instructions control the actions performed by the instructions. Extended mnemonics are provided that represent the TH value in the mnemonic rather than requiring it to be coded as a numeric operand.

- \text{dcbtct RA, RB, TH} \quad (\text{equivalent to: dcbt for TH values of } 0b00000 \text{ - } 0b00111); \quad \text{other TH values are invalid.}

- \text{dcbtds RA, RB, TH} \quad (\text{equivalent to: dcbt for TH values of } 0b00000 \text{ or } 0b01000 \text{ - } 0b01111); \quad \text{other TH values are invalid.}

- \text{dcbtt RA, RB} \quad (\text{equivalent to: dcbt for TH value of } 0b10000)

- \text{dcbna RA, RB} \quad (\text{equivalent to: dcbt for TH value of } 0b10001)

- \text{dcbtstct RA, RB, TH} \quad (\text{equivalent to: dcbtst for TH values of } 0b00000 \text{ or } 0b00000 \text{ - } 0b00111); \quad \text{other TH values are invalid.}

- \text{dcbtstds RA, RB, TH} \quad (\text{equivalent to: dcbtst for TH values of } 0b00000 \text{ or } 0b01000 \text{ - } 0b01111); \quad \text{other TH values are invalid.}

- \text{dcbtstt RA, RB} \quad (\text{equivalent to: dcbtst for TH value of } 0b10000)

A.2 Data Cache Block Flush Mnemonics

The L field in the Data Cache Block Flush instruction controls the scope of the flush function performed by the instruction, or the scope of the store function when \( L=6 \). Extended mnemonics are provided that represent the L value in the mnemonic rather than requiring it to be coded as a numeric operand.

- \text{dcbf RA, RB} \quad (\text{equivalent to: dcbf RA, RB, 0})

- \text{dcbfl RA, RB} \quad (\text{equivalent to: dcbf RA, RB, 1})

- \text{dcbflp RA, RB} \quad (\text{equivalent to: dcbf RA, RB, 4})

- \text{dcbfps RA, RB} \quad (\text{equivalent to: dcbf RA, RB, 6})

A.3 Or Mnemonics

The three register fields in the or instruction can be used to specify a hint indicating how the processor should handle stores caused by previous Store or dcbz instructions. An extended mnemonic is supported that represents the operand values in the mnemonic rather than requiring them to be coded as numeric operands.

- \text{miso} \quad (\text{equivalent to: or } 26,26,26)

A.4 Load And Reserve Mnemonics

The EH field in the Load And Reserve instructions provides a hint regarding the type of algorithm implemented by the instruction sequence being executed. Extended mnemonics are provided that allow the EH value to be omitted and assumed to be 0b0.

- \text{ibarx, ibarx, iwarx, idarx, and iqarx} serve as both basic and extended mnemonics. The Assembler will recognize these mnemonics with four operands as the basic form, and these mnemonics with three oper-
ands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

\[
\begin{align*}
\text{lbarx} & \quad \text{RT,RA,RB} \quad (\text{equivalent to: } \text{lbarx} \quad \text{RT,RA,RB,0}) \\
\text{lharc} & \quad \text{RT,RA,RB} \quad (\text{equivalent to: } \text{lharc} \quad \text{RT,RA,RB,0}) \\
\text{lwarx} & \quad \text{RT,RA,RB} \quad (\text{equivalent to: } \text{lwarx} \quad \text{RT,RA,RB,0}) \\
\text{ldarx} & \quad \text{RT,RA,RB} \quad (\text{equivalent to: } \text{ldarx} \quad \text{RT,RA,RB,0}) \\
\text{lqarx} & \quad \text{RT,RA,RB} \quad (\text{equivalent to: } \text{lqarx} \quad \text{RT,RA,RB,0}) \\
\text{sync} & \quad (\text{equivalent to: } \text{sync} \quad 0,0) \\
\text{sync} \ x & \quad (\text{equivalent to: } \text{sync} \quad x,0) \\
\text{hwsync} & \quad (\text{equivalent to: } \text{sync} \quad 0,0) \\
\text{lwsync} & \quad (\text{equivalent to: } \text{sync} \quad 1,0) \\
\text{ptesync} & \quad (\text{equivalent to: } \text{sync} \quad 2,0) \\
\text{phwsync} & \quad (\text{equivalent to: } \text{sync} \quad 4,0) \\
\text{plwsync} & \quad (\text{equivalent to: } \text{sync} \quad 5,0) \\
\text{stncisync} & \quad (\text{equivalent to: } \text{sync} \quad 1,1) \\
\text{stcisync} & \quad (\text{equivalent to: } \text{sync} \quad 0,2) \\
\text{stsync} & \quad (\text{equivalent to: } \text{sync} \quad 0,3) \\
\text{wait} & \quad (\text{equivalent to: } \text{wait} \quad 0,0) \\
\text{wait} \ rsrv & \quad (\text{equivalent to: } \text{wait} \quad 1,0) \\
\text{pause} \_short & \quad (\text{equivalent to: } \text{wait} \quad 2,0) \\
\text{mftb} \ Rx & \quad (\text{equivalent to: } \text{mftb} \ Rx,268) \\
& \quad \text{or: } \text{mfspr} \ Rx,268 \\
\text{mftbu} \ Rx & \quad (\text{equivalent to: } \text{mftb} \ Rx,269) \\
& \quad \text{or: } \text{mfspr} \ Rx,269 \\
\text{rfebb} & \quad (\text{equivalent to: } \text{rfebb} \ 1)
\end{align*}
\]

### A.5 Synchronize Mnemonics

The L and SC fields in the **Synchronize** instruction control the scope of the synchronization function performed by the instruction. Extended mnemonics are provided that represent the L and SC values in the mnemonic rather than requiring them to be coded as numeric operands.

**Note:** **sync** serves as both a basic and an extended mnemonic. The Assembler will recognize a **sync** mnemonic with two operands as the basic form, and a **sync** mnemonic with one operand or with no operand as an extended form. In the extended form with one operand the SC operand is omitted and assumed to be 0. In the extended form with no operand the L and SC operands are omitted and assumed to be 0.

### A.6 Wait Mnemonics

The WC field in the **wait** instruction determines the conditions under which instruction execution resumes. Extended mnemonics are provided that represent the WC and PL values in the mnemonic rather than requiring them to be coded as numeric operands.

**Note:** **wait** serves as both a basic and an extended mnemonic. The Assembler will recognize a **wait** mnemonic with two operands as the basic form and a **wait** mnemonic with one operand or with no operand as an extended form. In the extended form with one operand the PL operand is omitted and assumed to be 0. In the extended form with no operand the WC and PL operands are omitted and assumed to be 0.

### A.7 Move To/From Time Base Mnemonics

The tbr field in the **Move From Time Base** instruction specifies whether the instruction reads the entire Time Base or only the high-order half of the Time Base.

- mftb Rx \quad (equivalent to: mftb Rx,268)
- mftbu Rx \quad (equivalent to: mftb Rx,269)

### A.8 Return From Event-Based Branch Mnemonic

The S field in the **Return from Event-Based Branch** instruction specifies the value to which the instruction sets the GE field in the BESCR. Extended mnemonics are provided that represent the S value in the mnemonic rather than requiring it to be coded as a numeric operand.

- rfebb \quad (equivalent to: rfebb \ 1)

**Note:** **rfebb** serves as both a basic and an extended mnemonic. The Assembler will recognize this mnemonic with one operand as the basic form, and this mnemonic with no operands as the extended form. In the extended form the S operand is omitted and assumed to be 1.
Appendix B. Programming Examples for Sharing Storage

This appendix gives examples of how dependencies and the Synchronization instructions can be used to control storage access ordering when storage is shared between programs.

Many of the examples use extended mnemonics (e.g., bne, bne-, cmpw) that are defined in Appendix C of Book I.

Many of the examples use the Load And Reserve and Store Conditional instructions, in a sequence that begins with a Load And Reserve instruction and ends with a Store Conditional instruction (specifying the same storage location as the Load Conditional) followed by a Branch Conditional instruction that tests whether the Store Conditional instruction succeeded.

In these examples it is assumed that contention for the shared resource is low; the conditional branches are optimized for this case by using “+” and “-” suffixes appropriately.

The examples deal with words; they can be used for doublewords by changing all word-specific mnemonics to the corresponding doubleword-specific mnemonics (e.g., lwarx to ldarx, cmpw to cmpd).

In this appendix it is assumed that all shared storage locations are in storage that is Memory Coherence Required, and that the storage locations specified by Load And Reserve and Store Conditional instructions are in storage that is neither Write Through Required nor Caching Inhibited.

B.1 Atomic Update Primitives

This section gives examples of how the Load And Reserve and Store Conditional instructions can be used to emulate atomic read/modify/write operations.

An atomic read/modify/write operation reads a storage location and writes its next value, which may be a function of its current value, all as a single atomic operation. The examples shown provide the effect of an atomic read/modify/write operation, but use several instructions rather than a single atomic instruction.

Fetch and No-op

The “Fetch and No-op” primitive atomically loads the current value in a word in storage.

In this example it is assumed that the address of the word to be loaded is in GPR 3 and the data loaded are returned in GPR 4.

```
loop:
  lwax r4,0,r3 #load and reserve
  stwcx. r4,0,r3 #store old value if
    # still reserved
  bne- loop #loop if lost reservation
```

Note:

1. The stwcx, if it succeeds, stores to the target location the same value that was loaded by the preceding lwax. While the store is redundant with respect to the value in the location, its success ensures that the value loaded by the lwax is still the current value at the time the stwcx is executed.

Fetch and Store

The “Fetch and Store” primitive atomically loads and replaces a word in storage.

In this example it is assumed that the address of the word to be loaded and replaced is in GPR 3, the new value is in GPR 4, and the old value is returned in GPR 5.

```
loop:
  lwax r5,0,r3 #load and reserve
  stwcx. r4,0,r3 #store new value if
    # still reserved
  bne- loop #loop if lost reservation
```
Fetch and Add

The “Fetch and Add” primitive atomically increments a word in storage.

In this example it is assumed that the address of the word to be incremented is in GPR 3, the increment is in GPR 4, and the old value is returned in GPR 5.

```
loop:
  lwarx r5,0,r3 #load and reserve
  add r0,r4,r5 #increment word
  stwcx. r0,0,r3 #store new value if still res’ved
  bne- loop   #loop if lost reservation
```

Fetch and AND

The “Fetch and AND” primitive atomically ANDs a value into a word in storage.

In this example it is assumed that the address of the word to be ANDed is in GPR 3, the value to AND into it is in GPR 4, and the old value is returned in GPR 5.

```
loop:
  lwarx r5,0,r3 #load and reserve
  and r0,r4,r5 #AND word
  stwcx. r0,0,r3 #store new value if still res’ved
  bne- loop   #loop if lost reservation
```

Note:
1. The sequence given above can be changed to perform another Boolean operation atomically on a word in storage, simply by changing the `and` instruction to the desired Boolean instruction (`or`, `xor`, etc.).

Test and Set

This version of the “Test and Set” primitive atomically loads a word from storage, sets the word in storage to a nonzero value if the value loaded is zero, and sets the EQ bit of CR Field 0 to indicate whether the value loaded is zero.

In this example it is assumed that the address of the word to be tested is in GPR 3, the new value (nonzero) is in GPR 4, and the old value is returned in GPR 5.

```
loop:
  lwarx r5,0,r3 #load and reserve
  cmpwi r5,0 #done if word not equal to 0
  bne- exit   #skip if not
  stwcx. r5,0,r3 #store new value if still res’ved
  bne- loop   #loop if lost reservation
  mr r4,r6 #return value from storage
```

Compare and Swap

The “Compare and Swap” primitive atomically compares a value in a register with a word in storage, if they are equal stores the value from a second register into the word in storage, if they are unequal loads the word from storage into the first register, and sets the EQ bit of CR Field 0 to indicate the result of the comparison.

In this example it is assumed that the address of the word to be tested is in GPR 3, the comparand is in GPR 4 and the old value is returned there, and the new value is in GPR 5.

```
loop:
  lwarx r6,0,r3 #load and reserve
  cmpw r4,r6 #1st 2 operands equal?
  bne- exit   #skip if not
  stwcx. r5,0,r3 #store new value if still res’ved
  bne- loop   #loop if lost reservation
exit:
  mr r4,r6   #return value from storage
```

Notes:
1. The semantics given for “Compare and Swap” above are based on those of the IBM System/370 Compare and Swap instruction. Other architectures may define a Compare and Swap instruction differently.

2. “Compare and Swap” is shown primarily for pedagogical reasons. It is useful on machines that lack the better synchronization facilities provided by `lwarx` and `stwcx`. A major weakness of a System/370-style Compare and Swap instruction is that, although the instruction itself is atomic, it checks only that the old and current values of the word being tested are equal, with the result that programs that use such a Compare and Swap to control a shared resource can err if the word has been modified and the old value subsequently restored. The sequence shown above has the same weakness.

3. In some applications the second `bne` instruction and/or the `mr` instruction can be omitted. The `bne`- is needed only if the application requires that if the EQ bit of CR Field 0 on exit indicates “not equal” then (r4) and (r6) are in fact not equal. The `mr` is needed only if the application requires that if the comparands are not equal then the word from storage is loaded into the register with which it was compared (rather than into a third register). If either or both of these instructions is omitted, the resulting Compare and Swap does not obey System/370 semantics.
B.2 Lock Acquisition and Release, and Related Techniques

This section gives examples of how dependencies and the \textit{Synchronization} instructions can be used to implement locks, import and export barriers, and similar constructs.

B.2.1 Lock Acquisition and Import Barriers

An “import barrier” is an instruction or sequence of instructions that prevents storage accesses caused by instructions following the barrier from being performed before storage accesses that acquire a lock have been performed. An import barrier can be used to ensure that a shared data structure protected by a lock is not accessed until the lock has been acquired. A \textit{sync} instruction can be used as an import barrier, but the approaches shown below will generally yield better performance because they order only the relevant storage accesses.

B.2.1.1 Acquire Lock and Import Shared Storage

If \textit{lwarx} and \textit{stwcx} instructions are used to obtain the lock, an import barrier can be constructed by placing an \textit{isync} instruction immediately following the loop containing the \textit{lwarx} and \textit{stwcx}. The following example uses the “Compare and Swap” primitive to acquire the lock.

In this example it is assumed that the address of the lock is in GPR 3, the value indicating that the lock is free is in GPR 4, and the old value of the pointer is returned in GPR 5. The value to be added to the pointer is in GPR 6, and the address of the shared data structure is in GPR 9.

\begin{verbatim}
loop:
lwarx r6,0,r3,1 #load lock and reserve
cmpw r4,r6    #skip ahead if
bne- wait    # lock not free
stwcx. r5,0,r3 #try to set lock
bne- loop    #loop if lost reservation
isync        #import barrier
lwz r7,data1(r9)#load shared data
.
.
wait...     #wait for lock to free

The hint provided with \textit{lwarx} indicates that after the program acquires the lock variable (i.e., \textit{stwcx} is successful), it will release it (i.e., store to it) prior to another program attempting to modify it.

The second \textit{bne-} does not complete until CR0 has been set by the \textit{stwcx}. The \textit{stwcx} does not set CR0 until it has completed (successfully or unsuccessfully). The lock is acquired when the \textit{stwcx} completes successfully. Together, the second \textit{bne-} and the subsequent \textit{lwz}do not need \textit{isync} because the load uses the \textit{stwcx} that created the reservation used by the successful \textit{stwcx}. If the shared data structure is in storage that is neither Write Through Required nor Caching Inhibited, an \textit{lwsync} instruction can be used instead of the \textit{isync} instruction. If \textit{lwsync} is used, the load from “data1” may be performed before the \textit{stwcx}. But if the \textit{stwcx} fails, the branch is taken and the \textit{lwarx} is re-executed. If the \textit{stwcx} succeeds, the value returned by the load from “data1” is valid even if the load is performed before the \textit{stwcx}, because the \textit{lwsync} ensures that the load is performed after the instance of the \textit{lwarx} that created the reservation used by the successful \textit{stwcx}.

B.2.1.2 Obtain Pointer and Import Shared Storage

If \textit{lwarx} and \textit{stwcx} instructions are used to obtain a pointer into a shared data structure, an import barrier is not needed if all the accesses to the shared data structure depend on the value obtained for the pointer. The following example uses the “Fetch and Add” primitive to obtain and increment the pointer.

In this example it is assumed that the address of the pointer is in GPR 3, the value to be added to the pointer is in GPR 4, and the old value of the pointer is returned in GPR 5.

\begin{verbatim}
loop:
lwarx r5,0,r3 #load pointer and reserve
add r0,r4,r5 #increment the pointer
stwcx. r0,0,r3 #try to store new value
bne- loop    #loop if lost reservation
lwz r7,data1(r5) #load shared data

The load from “data1” cannot be performed until the pointer value has been loaded into GPR 5 by the \textit{lwarx}. The load from “data1” may be performed before the \textit{stwcx}. But if the \textit{stwcx} fails, the branch is taken and the value returned by the load from “data1” is discarded. If the \textit{stwcx} succeeds, the value returned by the load from “data1” is valid even if the load is performed before the \textit{stwcx}, because the load uses the pointer value returned by the instance of the \textit{lwarx} that created the reservation used by the successful \textit{stwcx}.

An \textit{isync} instruction could be placed between the \textit{bne-} and the subsequent \textit{lwz}, but no \textit{isync} is needed if all accesses to the shared data structure depend on the value returned by the \textit{lwarx}.\end{verbatim}
B.2.2 Lock Release and Export Barriers

An “export barrier” is an instruction or sequence of instructions that prevents the store that releases a lock from being performed before stores caused by instructions preceding the barrier have been performed. An export barrier can be used to ensure that all stores to a shared data structure protected by a lock will be performed with respect to any other processor before the store that releases the lock is performed with respect to that processor.

B.2.2.1 Export Shared Storage and Release Lock

A `sync` instruction can be used as an export barrier independent of the storage control attributes (e.g., presence or absence of the Caching Inhibited attribute) of the storage containing the shared data structure. Because the lock must be in storage that is neither Write Through Required nor Caching Inhibited, if the shared data structure is in storage that is Write Through Required or Caching Inhibited a `sync` instruction must be used as the export barrier.

In this example it is assumed that the shared data structure is in storage that is Caching Inhibited, the address of the lock is in GPR 3, the value indicating that the lock is free is in GPR 4, and the address of the shared data structure is in GPR 9.

```
stw r7,data1(r9)#store shared data (last)
sync #export barrier
stw r4,lock(r3)#release lock
```

The `sync` ensures that the store that releases the lock will not be performed with respect to any other processor until all stores caused by instructions preceding the `sync` have been performed with respect to that processor.

B.2.2.2 Export Shared Storage and Release Lock using `lwsync`

If the shared data structure is in storage that is neither Write Through Required nor Caching Inhibited, an `lwsync` instruction can be used as the export barrier. Using `lwsync` rather than `sync` will yield better performance in most systems.

In this example it is assumed that the shared data structure is in storage that is neither Write Through Required nor Caching Inhibited, the address of the lock is in GPR 3, the value indicating that the lock is free is in GPR 4, and the address of the shared data structure is in GPR 9.

```
stw r7,data1(r9)#store shared data (last)
lwsync #export barrier
stw r4,lock(r3)#release lock
```

The `lwsync` ensures that the store that releases the lock will not be performed with respect to any other processor until all stores caused by instructions preceding the `lwsync` have been performed with respect to that processor.

B.2.3 Safe Fetch

If a load must be performed before a subsequent store (e.g., the store that releases a lock protecting a shared data structure), a technique similar to the following can be used.

In this example it is assumed that the address of the storage operand to be loaded is in GPR 3, the contents of the storage operand are returned in GPR 4, and the address of the storage operand to be stored is in GPR 5.

```
lwz r4,0(r3)#load shared data
cmpw r4,r4 #set CR0 to "equal"
bne- $-8 #branch never taken
stw r7,0(r5)#store other shared data
```

An alternative is to use a technique similar to that described in Section B.2.1.2, by causing the `stw` to depend on the value returned by the `lwz` and omitting the `cmpw` and `bne-`. The dependency could be created by ANDing the value returned by the `lwz` with zero and then adding the result to the value to be stored by the `stw`. If both storage operands are in storage that is neither Write Through Required nor Caching Inhibited, another alternative is to replace the `cmpw` and `bne-` with an `lwsync` instruction.

```
lwz r4,0(r3)#load shared data
lwsync #export barrier
stw r7,0(r5)#store other shared data
```
B.3 List Insertion

This section shows how the \texttt{lwarx} and \texttt{stwcx} instructions can be used to implement simple insertion into a singly linked list. (Complicated list insertion, in which multiple values must be changed atomically, or in which the correct order of insertion depends on the contents of the elements, cannot be implemented in the manner shown below and requires a more complicated strategy such as using locks.)

The “next element pointer” from the list element after which the new element is to be inserted, here called the “parent element”, is stored into the new element, so that the new element points to the next element in the list; this store is performed unconditionally. Then the address of the new element is conditionally stored into the parent element, thereby adding the new element to the list.

In this example it is assumed that the address of the parent element is in GPR 3, the address of the new element is in GPR 4, and the next element pointer is at offset 0 from the start of the element. It is also assumed that the next element pointer of each list element is in a reservation granule separate from that of the next element pointer of all other list elements.

```
loop:
lwarx r2,0,r3 #get next pointer
stw r2,0(r4)#store in new element
lwsync or sync #order stw before stwcx
stwcx. r4,0,r3 #add new element to list
bne- loop #loop if stwcx. failed
```

In the preceding example, if two list elements have next element pointers in the same reservation granule then, in a multiprocessor, “livelock” can occur. (Livelock is a state in which processors interact in a way such that no processor makes forward progress.)

If it is not possible to allocate list elements such that each element’s next element pointer is in a different reservation granule, then livelock can be avoided by using the following, more complicated, sequence.

```
lwz r2,0(r3)#get next pointer
loop1:
  mr r5,r2 #keep a copy
  stw r2,0(r4)#store in new element
  sync #order stw before stwcx.
  and before lwarx

loop2:
lwarx r2,0,r3 #get it again
  cmpw r2,r5 #loop if changed (someone
  bne- loop1 # else progressed)
  stwcx. r4,0,r3 #add new element to list
  bne- loop2 #loop if failed
```

In the preceding example, livelock is avoided by the fact that each processor re-executes the \texttt{stw} only if some other processor has made forward progress.

B.4 Notes

The following notes apply to Section B.1 through Section B.3.

1. To increase the likelihood that forward progress is made, it is important that looping on \texttt{lwarx/stwcx} pairs be minimized. For example, in the “Test and Set” sequence shown in Section B.1, this is achieved by testing the old value before attempting the store; were the order reversed, more \texttt{stwcx} instructions might be executed, and reservations might more often be lost between the \texttt{lwarx} and the \texttt{stwcx}.

2. The manner in which \texttt{lwarx} and \texttt{stwcx} are communicated to other processors and mechanisms, and between levels of the storage hierarchy within a given processor, is implementation-dependent. In some implementations performance may be improved by minimizing looping on a \texttt{lwarx} instruction that fails to return a desired value. For example, in the “Test and Set” sequence shown in Section B.1, if the programmer wishes to stay in the loop until the word loaded is zero, he could change the “bne- exit” to “bne- loop”. However, in some implementations better performance may be obtained by using an ordinary Load instruction to do the initial checking of the value, as follows.

```
loop:
lwz r5,0(r3)#load the word
cmpwi r5,0 #loop back if word
bne- loop #  not equal to 0
lwarx r5,0,r3 #try again, reserving
cmpwi r5,0 # (likely to succeed)
  bne- loop
stwcx.r4,0,r3 #try to store non-0
bne- loop #loop if lost reserv'n
```

3. In a multiprocessor, livelock is possible if there is a Store instruction (or any other instruction that can clear another processor’s reservation; see Section 1.7.2.1) between the \texttt{lwarx} and the \texttt{stwcx} of a \texttt{lwarx/stwcx} loop and any byte of the storage location specified by the Store is in the reservation granule. For example, the first code sequence shown in Section B.3 can cause livelock if two list elements have next element pointers in the same reservation granule.
Book III:

Power ISA Operating Environment Architecture
Chapter 1. Introduction

1.1 Overview

Chapter 1 of Book I describes computation modes, document conventions, a general systems overview, instruction formats, and storage addressing. This chapter augments that description as necessary for the Power ISA Operating Environment Architecture.

1.2 Document Conventions

The notation and terminology used in Book I apply to this Book also, with the following substitutions.

- For “system alignment error handler” substitute “Alignment interrupt”.
- For “system data storage error handler” substitute “Data Storage interrupt”, “Hypervisor Data Storage interrupt”, or “Data Segment interrupt”, as appropriate.
- For “system error handler” substitute “interrupt”.
- For “system floating-point enabled exception error handler” substitute “Floating-Point Enabled Exception type Program interrupt”.
- For “system illegal instruction error handler” substitute “Hypervisor Emulation Assistance interrupt”.
- For “system instruction storage error handler” substitute “Instruction Storage interrupt”, “Hypervisor Instruction Storage interrupt”, or “Instruction Segment interrupt”, as appropriate.
- For “system privileged instruction error handler” substitute “Privileged Instruction type Program interrupt”.
- For “system service program” substitute “System Call interrupt” or “System Call Vectored interrupt”, as appropriate.
- For “system trap handler” substitute “Trap type Program interrupt”.
- For “system facility unavailable error handler” substitute “Facility Unavailable interrupt” or “Hypervisor Facility Unavailable interrupt.”

1.2.1 Definitions and Notation

The definitions and notation given in Book I and Book II are augmented by the following.

- **Threaded processor, single-threaded processor, thread**
  A threaded processor implements one or more “threads”, where a thread corresponds to the Book I/II concept of “processor”. That is, the definition of “thread” is the same as the Book I definition of “processor”, and “processor” as used in Books I and II can be thought of as either a single-threaded processor or as one thread of a multi-threaded processor. Except where the meaning is clear in context or the number of threads does not matter, the only unqualified uses of “processor” in Book III are in resource names (e.g. Processor Identification Register); such uses should be regarded as meaning “threaded processor”. The threads of a multi-threaded processor typically share certain resources, such as the hardware components that execute certain kinds of instructions (e.g., Fixed-Point instructions), certain caches, the address translation mechanism, and certain hypervisor and ultravisor resources.

- **real page**
  A unit of real storage that is aligned at a boundary that is a multiple of its size. The real page size is 4KB.

- **context of a program**
  The state (e.g., privilege and relocation) in which the program executes. The context is controlled by the contents of certain System Registers, such as the MSR and PTCR, of certain looksie buffers, such as the SLB and TLB, and of the Page Table.

- **performed**
  The definition of “performed” given in Section 1.1 of Book II is extended to apply to implicit storage accesses and to invalidations of entries in caches of information derived from address translation tables, as follows.
  - The definition of “load is performed” applies to accesses for performing address translation.
- The definition of “store is performed” applies to accesses for recording reference and change information.
- A TLB entry invalidation by thread T1 is performed with respect to thread T2 when the instruction that requested the invalidation has caused the specified entry, if present, to be made invalid in T2’s TLB, and similarly for invalidations of entries in other caches of information derived from tables used in address translation.

**exception**
An error, unusual condition, or external signal, that may set a status bit and may or may not cause an interrupt, depending upon whether the corresponding interrupt is enabled.

**interrupt**
The act of changing the machine state in response to an exception, as described in Chapter 7. “Interrupts” on page 1247.

- ultravisor interrupt
  An interrupt that forces the thread into ultravisor state by explicitly setting MSR$_SOHV$PR to 0b110 (see Section 4.2.1).
- hypervisor interrupt
  An interrupt that forces the thread into hypervisor state by explicitly setting MSR$_HV$PR to 0b10 and is not an ultravisor interrupt.
  All interrupts explicitly set MSR$_PR$ to 0.

**trap interrupt**
An interrupt that results from execution of a Trap instruction.

**“must”**
If software that runs in hypervisor state violates a rule that is stated using the word “must” (e.g., “this field must be set to 0”), and the rule pertains to the contents of a hypervisor resource, to executing an instruction that can be executed only in hypervisor state, or to accessing storage in real addressing mode, the results are undefined, and may include altering resources belonging to other partitions, causing the system to “hang”, etc. The same is true for software that runs in ultravisor state and violates a “must” rule pertaining to an ultravisor resource or instruction.

**hardware**
Any combination of hard-wired implementation, emulation assist, or interrupt for software assistance. In the last case, the interrupt may be to an architected location or to an implementation-dependent location. Any use of emulation assists or interrupts to implement the architecture is implementation-dependent.

**ultravisor privileged**
A term used to describe an instruction or facility that is available when and only when the thread is in ultravisor state.

**hypervisor privileged**
A term used to describe an instruction or facility that is available when and only when the thread is in hypervisor state.

---

**Programming Note**
Because ultravisor state is also a hypervisor state, hypervisor privileged instructions and facilities are also available when the thread is in ultravisor state. (The distinct privilege states in which a hypervisor privileged instruction or facility is available are: hypervisor non-ultravisor state, and ultravisor state.)

**privileged**
A term used to describe an instruction or facility that is available when and only when the thread is in privileged state.

---

**Programming Note**
Because hypervisor state is also a privileged state, privileged instructions and facilities are also available when the thread is in hypervisor state (and when the thread is in ultravisor state). (The distinct privilege states in which a privileged instruction or facility is available are: privileged non-hypervisor state, hypervisor non-ultravisor state, and ultravisor state.)

**privileged state and supervisor mode**
Used interchangeably to refer to a state in which privileged facilities are available.

**problem state and user mode**
Used interchangeably to refer to a state in which privileged facilities are not available.

$\|^, \|, \||, ...$ denotes a field that is reserved in an instruction, in a register, or in an architected storage table.

$\?, \??, \???,$ ... denotes a field that is implementation-dependent in an instruction, in a register, or in an architected storage table.

1.2.2 Reserved Fields
Book I’s description of the handling of reserved bits in System Registers, and of reserved values of defined fields of System Registers, applies also to the SLB. Book I’s description of the handling of reserved values of defined fields of System Registers applies also to architected storage tables (e.g., the Page Table).
Software should set reserved fields in the SLB and in architected storage tables to zero, because these fields may be assigned a meaning in some future version of the architecture.

Some fields of certain architected storage tables may be written to automatically by the hardware, e.g., Reference and Change bits in the Page Table. When the hardware writes to such a table, the following rules are obeyed.

- Unless otherwise stated, no defined field other than the one(s) specifically being updated are modified.
- Contents of reserved fields are either preserved or written as zero.

### 1.2.3 Deviations from the Sequential Execution Model

Additional exceptions to the rule that the thread obeys the sequential execution model, beyond those described in Section 2.2 of Book I and in the bullet defining “program order” in Section 1.1 of Book II, are the following.

- A System Reset or asynchronous Machine Check interrupt may occur. The determination of whether an instruction is required by the sequential execution model is not affected by the potential occurrence of a System Reset or asynchronous Machine Check interrupt. (The determination is affected by the potential occurrence of any other kind of interrupt.)

- A context-altering instruction is executed (Chapter 12, “Synchronization Requirements for Context Alterations” on page 1333). The context alteration need not take effect until the required subsequent synchronizing operation has occurred.

- A Reference and Change bit is updated by the thread. The update need not be performed with respect to that thread until the required subsequent synchronizing operation has occurred.

- A Branch instruction is executed and the branch is taken. The update of the Come-From Address Register (see Section 9.2 of Book III) need not occur until a subsequent context synchronizing operation has occurred.

### 1.2.4 Restricting Out-of-Order Execution

Because some classes of security exploits use side-effects of out-of-order execution to infer behavior of or receive information from programs, it may sometimes be necessary to limit out-of-order execution beyond what's necessary to maintain the appearance of compliance with the sequential execution model. This may include restrictions on the otherwise-permitted deviations from the sequential execution model described in Section 1.2.3 and Section 6.5. The Or Immediate instruction described in Section 5.4.3 can be used to create a barrier to out-of-order execution.

### 1.3 General Systems Overview

The hardware contains the sequencing and processing controls for instruction fetch, instruction execution, and interrupt action. Most implementations also contain data and instruction caches. Instructions that the processing unit can execute fall into the following classes:

- instructions executed in the Branch Facility
- instructions executed in the Fixed-Point Facility
- instructions executed in the Floating-Point Facility
- instructions executed in the Vector Facility

Almost all instructions executed in the Branch Facility, Fixed-Point Facility, Floating-Point Facility, and Vector Facility are nonprivileged and are described in Book I. Book II may describe additional nonprivileged instructions (e.g., Book II describes some nonprivileged instructions for cache management). Instructions related to the privileged state, control of hardware resources, control of the storage hierarchy, and all other privileged instructions are described here or are implementation-dependent.

### 1.4 Exceptions

The following augments the exceptions defined in Book I that can be caused directly by the execution of an instruction:

- the execution of a floating-point instruction when MSR_PP=0 (Floating-Point Unavailable interrupt)
- an attempt to modify a hypervisor resource when the thread is in privileged but non-hypervisor state (see Chapter 2), or an attempt to execute a hypervisor-only instruction (e.g., `tlbie`) when the thread is in privileged but non-hypervisor state
- an attempt to modify an ultravisor resource when the thread is in privileged but non-ultravisor state (see Chapter 3), or an attempt to execute an ultravisor-only instruction (e.g., `urfd`, `msgsndu`, `msgclru`) when the thread is in privileged but non-ultravisor state
- the execution of a traced instruction (Trace interrupt)
- the execution of a Vector instruction when the vector facility is unavailable (Vector Unavailable interrupt)
1.5 Synchronization

The synchronization described in this section refers to the state of the thread that is performing the synchronization.

1.5.1 Context Synchronization

An instruction or event is context synchronizing if it satisfies the requirements listed below. Such instructions and events are collectively called context synchronizing operations. The context synchronizing operations are the isync instruction, the System Linkage instructions, the mtmsr[d] instructions with L=0, and most interrupts (see Section 7.4).

1. The operation causes instruction dispatching (the issuance of instructions by the instruction fetching mechanism to any instruction execution mechanism) to be halted.

2. The operation is not initiated or, in the case of isync, does not complete, until all instructions that precede the operation have completed to a point at which they have reported all exceptions they will cause.

3. The operation ensures that the instructions that precede the operation will complete execution in the context (privilege, relocation, storage protection, etc.) in which they were initiated, except that the operation has no effect on the context in which the associated Reference and Change bit updates are performed.

4. If the operation directly causes an interrupt (e.g., sc directly causes a System Call interrupt) or is an interrupt, the operation is not initiated until no exception exists having higher priority than the exception associated with the interrupt (see Section 7.9).

5. The operation ensures that the instructions that follow the operation will be fetched and executed in the context established by the operation. (This requirement dictates that any prefetched instructions be discarded and that any effects and side effects of executing them out-of-order also be discarded, except as described in Section 6.5, “Performing Operations Out-of-Order”.)

Programming Note

A context synchronizing operation is necessarily execution synchronizing; see Section 1.5.2.

Unlike the Synchronize instruction, a context synchronizing operation does not affect the order in which storage accesses are performed.

Item 2 permits a choice only for isync (and [p]hwsync and ptesync; see Section 1.5.2) because all other execution synchronizing operations also alter context.
1.5.2 Execution Synchronization

An instruction is \textit{execution synchronizing} if it satisfies items 2 and 3 of the definition of context synchronization (see Section 1.5.1). [\texttt{phw}sync and \texttt{ptesync} are treated like \texttt{isync} with respect to item 2. The execution synchronizing instructions are \texttt{phw}sync, \texttt{ptesync}, the \texttt{mtmsr[d]} instructions with \( L = 1 \), and all context synchronizing instructions.

\begin{center}
\textbf{Programming Note}

Unlike a context synchronizing operation, an execution synchronizing instruction does not ensure that the instructions following that instruction will execute in the context established by that instruction. This new context becomes effective sometime after the execution synchronizing instruction completes and before or at a subsequent context synchronizing operation.
\end{center}
Chapter 2. Logical Partitioning (LPAR) and Thread Control

2.1 Overview

The Logical Partitioning (LPAR) facility permits threads and portions of real storage to be assigned to logical collections called partitions, such that a program executing on a thread in one partition cannot interfere with any program executing on a thread in a different partition. This isolation can be provided for both problem state and privileged non-hypervisor state programs, by using a layer of trusted software, called a hypervisor program (or simply a "hypervisor"), and the resources provided by this facility to manage system resources. (A hypervisor is a program that runs in hypervisor state; see below.)

The number of partitions supported is implementation-dependent.

A thread is assigned to one partition at any given time. A thread can be assigned to any given partition without consideration of the physical configuration of the system (e.g., shared registers, caches, organization of the storage hierarchy), except that threads that share certain hypervisor resources may need to be assigned to the same partition; see Section 2.6. The registers and facilities used to control Logical Partitioning are listed below and described in the following subsections.

Except in the following subsections, references to the "operating system" in this document include the hypervisor unless otherwise stated or obvious from context.

2.2 Logical Partitioning Control Register (LPCR)

The contents of the LPCR control a number of aspects of the operation of the thread with respect to a logical partition. Below are shown the bit definitions for the LPCR.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:3</td>
<td>Virtualization Control (VC)</td>
</tr>
<tr>
<td></td>
<td>Controls the virtualization of partition memory for partitions that use HPT translation. This field contains three subfields, VPM, ISL, and KBV. Accesses that are initiated in hypervisor state (i.e., MSR_hv PR=0b10) are performed as if VPM=0 and KBV=0. (ISL applies regardless of privilege.)</td>
</tr>
<tr>
<td>0</td>
<td>Reserved</td>
</tr>
<tr>
<td>1</td>
<td>Virtualized Partition Memory (VPM)</td>
</tr>
<tr>
<td></td>
<td>Controls whether VPM mode is enabled when address translation is enabled as specified below.</td>
</tr>
<tr>
<td></td>
<td>0 - VPM mode disabled</td>
</tr>
<tr>
<td></td>
<td>1 - VPM mode enabled</td>
</tr>
<tr>
<td></td>
<td>When address translation is disabled, VPM mode is enabled. See Section 6.7.2, &quot;Virtualized Partition Memory (VPM) Mode&quot;, and Section 6.7.3.3, &quot;Virtual Real Mode Addressing Mechanism&quot;, for additional information on VPM mode.</td>
</tr>
</tbody>
</table>

**Programming Note**

VPM must be set to zero by hypervisors that use HPT translation and want to receive storage interrupts from applications running directly under them as DSIs and ISIs (instead of HDSIs and HISIs).

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>2</td>
<td>Ignore SLB Large Page Specification (ISL)</td>
</tr>
<tr>
<td></td>
<td>Controls whether ISL mode is enabled as specified below.</td>
</tr>
<tr>
<td></td>
<td>0 - ISL mode disabled</td>
</tr>
<tr>
<td></td>
<td>1 - ISL mode enabled</td>
</tr>
<tr>
<td></td>
<td>When ISL mode is enabled and address translation is enabled, address translation is performed as if the contents of SLB_{LLL} and PRTE_{STPS} were 0b000. When address translation is disabled, the setting of the ISL bit has no effect. ISL mode has no effect on SLB, TLB, and ERAT entry invalidations.</td>
</tr>
</tbody>
</table>
caused by \textit{slbie}, \textit{slbieg}, \textit{slbia}, \textit{slbiag}, \textit{tlbie}, and \textit{tlbiel}.

\textbf{Programming Note}:
Specifying that L|LP = 0b000 in \text{PATE\textsubscript{PS}} has the same effect on address translation when translation is disabled as enabling ISL mode when translation is enabled.

ISL mode is needed when a partition is running with address translation enabled because translation uses the SLB, and the contents of the SLB are controlled by the operating system and should not be modified by the hypervisor. ISL mode is not needed when a partition is running with address translation disabled since Virtual Real Mode address translation uses \text{PATE\textsubscript{PS}}, which is not visible to the operating system and is in complete control of the hypervisor.

Any PTE with a base page size of 4K satisfies the page size portion of the match criteria for HPT search.

\textbf{3 Key-Based Virtualization (KBV)}
Controls whether Key-Based Virtualization is enabled as specified below.

0 - KBV is disabled
1 - KBV is enabled

When KBV is enabled and MSR\textsubscript{HV|PR} = 0b10, Virtual Page Class Key Storage Protection exceptions that occur on storage operand accesses when VPM = 0 cause Hypervisor Data Storage interrupts.

\textbf{Programming Note}:
Key-Based Virtualization provides an efficient means for the hypervisor to intercept storage references, e.g. MMIO, that must be emulated. (The corresponding behavior for instruction fetching is not desired.) Virtual Page Class Key Storage Protection exceptions not handled by the hypervisor should be reflected to the operating system at its Data Storage interrupt vector with the hypervisor having set DSISR\textsubscript{42}.

\textbf{9:11 Default Prefetch Depth (DPFD)}
The DPFD field is used as the default prefetch depth for data stream prefetching when DSCR\textsubscript{DPFD} = 0; see page 1054.

\textbf{12:16 Reserved}

\textbf{17:19 Power-saving mode Exit Cause Enable (Upper Section) (PECE\textsubscript{U})}

\textbf{17 Hypervisor Virtualization Exit Enable}
0 When the \textit{stop} instruction is executed with PSSCR\textsubscript{EC} = 1, Hypervisor Virtualization exceptions are not enabled to cause exit from power-saving mode.
1 When the \textit{stop} instruction is executed with PSSCR\textsubscript{EC} = 1, Hypervisor Virtualization exceptions are enabled to cause exit from power-saving mode.

\textbf{18:19 Reserved}

\textbf{37 Hypervisor Alternate Interrupt Location (HAIL)}
Controls the effective address offset, or alternate effective address for System Call Vectored, of the interrupt handler and the relocation mode in which it begins execution for all interrupts received in hypervisor state except those subject to the overrides described below.

0 The interrupt is taken with MSR\textsubscript{IR DR} = 0b00 and no effective address offset or alternate effective address.
1 The interrupt is taken with MSR\textsubscript{IR DR} = 0b11. If the interrupt is not System Call Vectored, an effective address offset of 0xc000_0000_0000_4000 is applied. System Call Vectored uses an alternate effective address of 0xc000_0000_0000_3||LEV||0b0_0000.

The overrides mentioned above are as follows. The list should be read from the top down; the first item matching a given situation applies.
- If the interrupt is received in ultrvisor state, the interrupt is taken as if LPCR\textsubscript{HAIL} = 0.
- Machine Check, System Reset, and Hypervisor Maintenance interrupts are taken as if LPCR\textsubscript{HAIL} = 0.
- If the interrupt occurs when MSR\textsubscript{HV} = 1 and either MSR\textsubscript{IR} = 0 or MSR\textsubscript{DR} = 0, the interrupt is taken as if LPCR\textsubscript{HAIL} = 0.

\textbf{38 Interrupt Little-Endian (ILE)}
The contents of the ILE bit are copied into MSR\textsubscript{LE} by interrupts that set MSR\textsubscript{HV} to 0 (see
Section 7.5), to establish the Endian mode for the interrupt handler.

**Alternate Interrupt Location (AIL)**

Controls the effective address offset, or alternate effective address for System Call Vectored, of the interrupt handler and the relocation mode in which it begins execution for all interrupts received in privileged non-hypervisor state except those subject to the overrides described below.

- **0**: The interrupt is taken with MSR\textsubscript{IR} \textsubscript{DR} = 0b00 and no effective address offset or alternate effective address.
- **1**: Reserved
- **2**: Reserved
- **3**: The interrupt is taken with MSR\textsubscript{IR} \textsubscript{DR} = 0b11. If the interrupt is not System Cal Vectored, an effective address offset of 0xc00_0000_0000_4000 is applied. System Call Vectored uses an alternate effective address of 0xc00_0000_0000_3 || LEV || 0b0_0000.

The overrides mentioned above are as follows. The list should be read from the top down; the first item matching a given situation applies.

- If the interrupt occurs when MSR\textsubscript{IR}=0 or MSR\textsubscript{DR}=0, the interrupt is taken as if LPCR\textsubscript{AIL}=0.

**Use Process Table (UPRT)**

Controls whether Process Tables are used. For a radix-using partition, UPRT must be set to 1. For a paravirtualized HPT partition, UPRT is set to 1 when the operating system does not require the use of the legacy software-managed SLB.

- **0**: Process Table is not used. (Software-managed SLB in use, for paravirtualized HPT partition.)
- **1**: Process Table is used. (Segment Table in use, for paravirtualized HPT partition.)

**Programming Note**

The POWER9 processor operates as though LPCR\textsubscript{UPRT}=0 for partitions that use HPT translation, requiring operating systems to fully manage the SLB in software. Nonetheless, operating systems may need to maintain segment tables for use by accelerators.

**Enhanced Virtualization (EVIRT)**

Controls whether Enhanced Virtualization is enabled, as specified below.

- **0**: Enhanced Virtualization is disabled: attempts to execute hypervisor-privileged instructions or access hypervisor resources, or PTCR, DAWRn, DAWRXn, or CIABR when they are ultravisor resources, in privileged non-hypervisor state cause a Privileged Instruction type Program interrupt; attempts to access undefined SPR numbers (using mt\textsubscript{spr} or mfs\textsubscript{spr}) other than 0, 4, 5, and 6 in privileged state are treated as no-ops.

- **1**: Enhanced Virtualization is enabled: attempts to execute hypervisor-privileged instructions or access hypervisor resources, or PTCR, DAWRn, DAWRXn, or CIABR when they are ultravisor resources, in privileged non-hypervisor state cause a Hypervisor Emulation Assistance interrupt; attempts to access undefined SPR numbers (using mt\textsubscript{spr} or mfs\textsubscript{spr}) other than 0, 4, 5, and 6 in privileged state cause a Hypervisor Emulation Assistance interrupt.

**Programming Note**

Running with LPC\textsubscript{REVIRT}=1 facilitates support of nested hypervisors (hypervisors that run with MSR\textsubscript{HV} \textsubscript{PR}=0b00 and have their use of hypervisor resources virtualized by a higher level hypervisor); see the relevant Programming Note in Section 7.5.18, “Hypervisor Emulation Assistance Interrupt”. It also permits emulation of new SPRs on designs that do not support them in hardware.

All accesses to the reserved noop SPRs (808-811) are always treated as noops, independent of the value of EVIRT.

**Host Radix (HR)**

Indicates whether the hypervisor uses Radix Tree translation for the partition, as specified below.

- **0**: hypervisor uses HPT translation for this partition.
- **1**: hypervisor uses Radix Tree translation for this partition.

The hypervisor must program HR to match the Host Radix bit in the Partition Table Entry for the partition indicated by LPIDR. If the values do not match and the thread is not in hypervisor real addressing mode or ultravisor real addressing mode, the results are undefined.
**Programming Note**

HR is duplicated in the LPCR because there are times such as immediately after a partition swap when it is difficult for hardware to quickly access the PATE.

The translation mode for the hypervisor is the same as the translation mode of the partition the hypervisor is serving. This is necessary for consistent, well-defined behavior when a hypervisor concurrently serves partitions using both translation modes, and it creates a requirement that HR=1 in the PATE for LPID=0 when Radix Tree Translation partitions exist in the system, because of the effLPID construct. The architecture may refer to the translation mode of the hypervisor rather than the HR value for the partition when the relationship to the hypervisor matters.

44 Reserved

45 **Online** (ONL)

0 The PURR and SPURR do not increment.
1 The PURR and SPURR increment.

**Programming Note**

Typically, the hypervisor sets the ONL bit to 0 when the thread is not in a power-saving mode, is not performing useful work, and is available for use. The hypervisor may take the state of the ONL bit into account when making course-grain load balancing and power management decisions.

46 **Large Decrementer** (LD)

0 Large Decrementer mode is not enabled.
1 Large Decrementer mode is enabled.

See Section 8.4 for additional information.

47:51 **Power-saving mode Exit Cause Enable (Lower Section)** (PECE<sub>L</sub>)

47 **Privileged Doorbell Exit Enable**

0 When the **stop** instruction is executed with PSSCREC=1, Directed Privileged Doorbell exceptions are not enabled to cause exit from power-saving mode.
1 When the **stop** instruction is executed with PSSCREC=1, Directed Privileged Doorbell exceptions are enabled to cause exit from power-saving mode.

48 **Hypervisor Doorbell Exit Enable**

0 When the **stop** instruction is executed with PSSCREC=1, Directed Hypervisor Doorbell exceptions are not enabled to cause exit from power-saving mode.
1 When the **stop** instruction is executed with PSSCREC=1, Directed Hypervisor Doorbell exceptions are enabled to cause exit from power-saving mode.

49 **External Exit Enable**

0 When the **stop** instruction is executed with PSSCREC=1, External exceptions are not enabled to cause exit from power-saving mode.
1 When the **stop** instruction is executed with PSSCREC=1, External exceptions are enabled to cause exit from power-saving mode.

50 **Decrementer Exit Enable**

0 When the **stop** instruction is executed with PSSCREC=1, Decrementer exceptions are not enabled to cause exit from power-saving mode.
1 When the **stop** instruction is executed with PSSCREC=1, Decrementer exceptions are enabled to cause exit from power-saving mode. (Decrementer exceptions do not occur if the state of the Decrementer is not maintained and updated as if the thread was not in power-saving mode.)

51 **Other Exit Enable**

0 When the **stop** instruction is executed with PSSCREC=1, Machine Check, Hypervisor Maintenance, and certain implementation-specific exceptions are not enabled to cause exit from power-saving mode.
1 When the **stop** instruction is executed with PSSCREC=1, Machine Check, Hypervisor Maintenance, and certain implementation-specific exceptions are enabled to cause exit from power-saving mode.

If the state of the PECE field is lost during power-saving mode, implementations must provide the means to exit power-saving mode upon the occurrence of a System Reset exception and any of the exceptions that were enabled by the PECE field when the **stop** instruction was executed. In addition, they may also exit power-saving mode on exceptions that were disabled by the PECE field as well. See Section 7.5.1 and Section 7.5.2 for additional information about exit from power-saving mode.

52 **Mediated External Exception Request** (MER)

0 A Mediated External exception is not requested.
A Mediated External exception is requested.

The exception effects of this bit are said to be consistent with the contents of this bit if one of the following statements is true.
- LPCRMER = 1 and a Mediated External exception exists.
- LPCRMER = 0 and a Mediated External exception does not exist.

A context synchronizing instruction or event that is executed or occurs when LPCRMER = 0 ensures that the exception effects of LPCRMER are consistent with the contents of LPCRMER. Otherwise, when an instruction changes the contents of LPCRMER, the exception effects of LPCRMER become consistent with the new contents of LPCRMER reasonably soon after the change.

**Programming Note**

LPCRMER provides a means for the hypervisor to direct an external exception to a partition independent of the partition's MSR_EE setting. (When MSR_EE=0, it is inappropriate for the hypervisor to deliver the exception.) Using LPCRMER, the partition can be interrupted upon enabling external interrupts. Without using LPCRMER, the hypervisor must check the state of MSR_EE whenever it gets control, which will result in less timely delivery of the exception to the partition.

Guest Translation Shootdown Enable (GTSE)

Controls whether the operating system is permitted to use tlbie, slbieg, and slbiag directly, or must issue a system call to the hypervisor.
- 0 Guest is not permitted to use tlbie, slbieg, slbiag, tlbsync, and slbsync.
- 1 Guest is permitted to use tlbie, slbieg, slbiag, tlbsync, and slbsync.

**Programming Note**

An operating system that uses HPT translation must know whether VPM is active in order to invalidate the translation for a specific page using tlbie[]. See the related Programming Notes in the descriptions of tlbie and tlbiel.

Translation Control (TC)

0 The secondary Page Table search is enabled.
1 The secondary Page Table search is disabled.

**Reserved**

Hypervisor External Interrupt Control (HEIC)

0 Direct External interrupts can occur in hypervisor state.
1 Direct External interrupts cannot occur in hypervisor state.

**Programming Note**

By setting HEIC=1, the Hypervisor Interrupt Virtualization handler can prevent External interrupts from occurring during the Hypervisor Virtualization interrupt handler. See Section 7.5.7.1.

Logical Partitioning Environment Selector (LPES)

0 External interrupts set the HSRRs, set MSR_HV to 1, and leave MSR_RI unchanged.
1 External interrupts set the SRRs, set MSR_RI to 0, and leave MSR_HV unchanged.

**Programming Note**

LPES = 1 should be used by operating systems not running under a hypervisor, so that external interrupts are directed to the SRRs rather than to the HSRRs.

Hypervisor Virtualization Interrupt Conditionally Enable (HVICE)

0 Hypervisor Virtualization interrupts are disabled.
1 Hypervisor Virtualization interrupts are enabled if permitted by MSR_EE, MSR/fwlink, and MSR_HV; see Section 7.5.21.

Hypervisor Decrementer Interrupt Conditionally Enable (HDICE)

0 Hypervisor Decrementer interrupts are disabled.
1 Hypervisor Decrementer interrupts are enabled if permitted by MSR_EE, MSR_HV, and MSR_HV; see Section 7.5.12 on page 1275.
See Section 7.5 on page 1260 for a description of how the setting of LPES affects the processing of interrupts.

### 2.3 Hypervisor Real Mode Offset Register (HRMOR)

The layout of the Hypervisor Real Mode Offset Register (HRMOR) is shown in Figure 1 below.

#### Figure 1. Hypervisor Real Mode Offset Register

All other fields are reserved.

The supported HRMO values are the non-negative multiples of $2^r$, where $r$ is an implementation-dependent value and $12 \leq r \leq 26$.

The contents of the HRMOR affect how some storage accesses are performed as described in Section 6.7.3 on page 1180 and Section 6.7.5 on page 1184.

### 2.4 Logical Partition Identification Register (LPIDR)

The layout of the Logical Partition Identification Register (LPIDR) is shown in Figure 2 below.

#### Figure 2. Logical Partition Identification Register

The contents of the LPIDR identify the partition to which the thread is assigned, affecting some aspects of translation. The number of LPIDR bits supported is implementation-dependent.

### 2.5 Processor Compatibility Register (PCR)

The layout of the Processor Compatibility Register (PCR) is shown in Figure 3 below.

#### Figure 3. Processor Compatibility Register

High-order PCR bits are assigned to control the availability of facilities. Low-order PCR bits are assigned to control the availability of resources that are new in a specified version of the Architecture. The two types of bits can interact. For example, if a facility is created in one version and extended in the next, the high-order bit enables the portion of the facility that was defined in the version of the architecture enabled in the low-order bits.

Each defined bit in the PCR controls whether certain instructions, SPRs, and other related facilities are available in problem state. Except as specified elsewhere in this section, the PCR has no effect on facilities when the thread is not in problem state, or on privileged facilities when the thread is in problem state. Facilities that are made unavailable by the PCR are treated as follows when the thread is in problem state:

- Except for `mffsl`, `mffsce`, `mffsdn`, `mffsdrn`, `mffsm`, and `mffsni`, non-privileged instructions are treated as illegal instructions.
- `mffsl`, `mffsce`, `mffsdn`, `mffsdrn`, `mffsm`, and `mffsni` perform as if they are an `mffs` instruction.
- SPRs are treated as if they were not defined for the implementation.
- The "reserved SPRs" (see Section 1.3.3 of Book I) are treated as not defined for the implementation.
- Fields in instructions are treated as if they were 0s except for the `L` field in `paste`.
- Values of fields in instructions cause the instruction to be treated as an invalid form of the instruction.
- Unless the third item of this list applies, bits in system registers read back 0s for `mfspr` and `mtspr` operations have no effect on their values, except as described immediately below for bits 44:45 of the XER.

For bits 44:45 of the XER, two pairs of bits are provided, an "OV32-CA32" bit pair for `XEROV32` and `XERCA32` and a "reserved" bit pair for legacy XER bits 44:45 behavior.

Which bit pair is read by `mfxer` is controlled by the PCR. `mtxer` writes to both bit pairs, independent of the PCR. `mcrxr` reads the "OV32-CA32" bit pair.
Each bit in the “OV32-CA32” bit pair is implicitly set by instructions that implicitly set their respective XER_{OV} or XER_{CA}, independent of the PCR. The “reserved” bit pair for bits 44:45 of the XER are not altered by these instructions, independent of the PCR.

Programming Note

The “reserved” bit pair does not conform to the usual rules for reading (mfspr) reserved bits in registers (see Section 1.3.3 of Book I) because some early implementations used bits 44:45 of the XER for implementation-specific purposes. On these implementations, and on subsequent implementations that implemented versions of the architecture that precede V. 3.0, mfxer returned the contents of the bits, despite that the bits were defined as reserved.

A defined bit in the PCR may also control whether certain instructions, SPRs, and other related facilities are available in a privileged state (MSR{\text{PR}=0}). Affected facilities will be specifically annotated.

Programming Note

When a bit in a system register is made unavailable by the PCR, mtspr operations performed on the register in problem state have no effect on the value of the bit regardless of the privilege state in which the register may subsequently be read.

A PCR bit may also determine how an instruction field value is interpreted or may define other behavior as specified in the bit definitions below.

As described in more detail below, the value 1 in a defined bit in the PCR makes the affected resources unavailable and the value 0 makes them available.

The initial state of the PCR is all 0s. In this state, all instructions and facilities supported by the processor are available in all privilege states.

Programming Note

Facilities that can be disabled in problem state by the PCR that also have enable bits in either the MSR or [H]FSCR include the BHRB instructions, event-based branch instructions, TAR, DSCR at SPR 3, SIER, MMCR2, the event-based branch instructions, and certain Floating-Point, Vector, and VSX instructions. When any of these facilities are made unavailable in problem state by the PCR, the corresponding [Hypervisor] Facility Unavailable, Floating-Point Unavailable, Vector, or VSX unavailable interrupts do not occur when the facility is accessed in problem state. Note, however, that the PCR does not affect privileged accesses, and thus any Hypervisor Facility Unavailable, Floating-Point Unavailable, Vector unavailable, or VSX unavailable interrupts that are specified to occur as a result of privileged accesses occur regardless of the PCR value.

Programming Note

Hypervisors written for a given version of the architecture generally cannot support facilities that are defined in a subsequent version of the architecture if those facilities have new state that would need to be preserved across context switches. (In the absence of such state, support may or may not be possible.) Therefore, hypervisors will set to 1 all PCR bits that are reserved in the given version of the architecture.

The PCR has no effect on the setting of the MSR and [H]SRR1 by interrupts (and of the Count Register by the System Call Vectored interrupt), and by the rfscv.
Because the PCR has no effect on privileged instructions except as specified above, privileged instructions that are available on newer implementations but not available on older implementations will behave differently when the thread is in problem state. On older implementations, a Hypervisor Emulation Assistance interrupt will occur because the instruction is undefined; on newer implementations, a Privileged Instruction type Program interrupt will occur because the instruction is implemented.

In future versions of the architecture, in general the lowest-order reserved bit of the PCR will be used to control the availability of the instructions and related resources that are new in that version of the architecture; the name of the bit will correspond to the previous version of the architecture (i.e., the newest version in which the instructions and related resources were not available).

In these future versions of the architecture, there will be a requirement that if any bit of the low-order defined bits is set to 1 then all higher-order bits of the defined low-order bits must also be set to 1, and the architecture version with which the implementation appears to comply, in problem state, will be the version corresponding to the name of the lowest-order 1 bit in the set of defined low-order PCR bits, or the current architecture version if none of these bits are 1. Also, in general the highest-order reserved bits will be used to control the availability of sets of instructions and related resources having the requirement that their availability be independent of versions of the architecture.
The bit definitions for the PCR are shown below.

<table>
<thead>

</tr>
<tr>
<td></td>
<td>1  The instructions listed in Table 1 are not available.</td>
</tr>
<tr>
<td>4:58</td>
<td>Reserved</td>
</tr>
<tr>
<td>59</td>
<td>Version 3.0 (v3.0)</td>
</tr>
<tr>
<td></td>
<td>When MSRPR=1 (i.e., problem state), this bit controls the availability of the following instructions, facilities, and behaviors that were newly available in problem state in the version of the architecture subsequent to Version 3.0.</td>
</tr>
<tr>
<td></td>
<td>- The instructions listed in Table 2 on page 1131</td>
</tr>
<tr>
<td></td>
<td>- The value 0 in bit 10 of the paste instruction. When this value is unavailable, attempt to execute a paste instruction with bit 10 set to 0 causes a Hypervisor Emulation Assistance interrupt in all privilege levels. (Although the L field is new, it has behavior more like a new value of a field because its pre-existing value was 1 instead of 0, and there is a need to treat the new value as causing an illegal instruction behavior instead of being ignored.)</td>
</tr>
<tr>
<td></td>
<td>- The ability to perform a data transfer from one storage location to another or to another system. When this function is unavailable, attempting to use it in any privilege state causes a DSI or HDSI on the paste instruction, setting [H]DSISR\textsubscript{60} as would occur under Version 3.0 of the architecture. See the latest revision of Version 3.0 of the architecture for details.</td>
</tr>
<tr>
<td></td>
<td>- SIER2, SIER3 and MMCR3</td>
</tr>
<tr>
<td></td>
<td>0  The instructions, behaviors, and facilities listed above are available.</td>
</tr>
<tr>
<td></td>
<td>Any word in storage fetched as an instruction having a primary opcode of 0b0000001 is treated as the prefix of a prefixed instruction and the next sequential word in storage is treated as the suffix of that prefixed instruction.</td>
</tr>
<tr>
<td></td>
<td>1  The instructions, behaviors, and facilities listed above are unavailable.</td>
</tr>
</tbody>
</table>

Any word in storage fetched as an instruction having a primary opcode of 0b0000001 is treated as an illegal word instruction.

Because this bit affects whether prefixed instructions are treated as illegal word instructions, it may affect how the Hypervisor Emulation Assist interrupt sets HSRR\textsubscript{134} and HEIR. If this bit is set to 1, then the MMA bit must also be set to 1.

When MSRPR=1 and MMCR0\textsubscript{PMCC}=0b00, this bit controls whether read permission on Group B Performance Monitor registers (i.e., SIER, SIAR, SDAR, and MMCR\textsubscript{1} at SPR numbers 768, 780, 781 and 782, respectively) specified in Version 3.0 of the architecture is further conditional on MMCR\textsubscript{0 PMCC\textsubscript{EXT}} bit or not.

- 0 mfspr availability on the mentioned registers is conditional on MMCR\textsubscript{0 PMCC\textsubscript{EXT}} bit. |
| 1  mfspr on the mentioned registers is available in problem state without further conditions. |

Version 2.07 (v2.07)

When MSR\textsubscript{PR}=1 (i.e., problem state), this bit controls the availability of the following instructions, facilities, and behaviors that were newly available in problem state in the version of the architecture subsequent to Version 2.07.

- The instructions listed in Table 3 on page 1134 |
| scv |
| 0  The instructions, behaviors, and facilities listed above are available. |
| mfxer reads the contents of the “OV32-CA32” bit pair for XER bits 44:45. |
| 1  The instructions, behaviors, and facilities listed above are unavailable. |
| mfxer reads the contents of the “reserved” bit pair for XER bits 44:45. |
| 0  mcrxrx is available. |
| mfxer reads the contents of the “OV32-CA32” bit pair for XER bits 44:45. |
| 1  mcrxrx is unavailable. |
**mfxer** reads the contents of the "reserved" bit pair for XER bits 44:45. If this bit is set to 1, then the v3.0 bit must also be set to 1.

Table 3: Instructions controlled by the v2.07 bit (Sheet 3 of 6)
2.6 Other Hypervisor Resources

In addition to the resources described in the preceding sections, all hypervisor privileged instructions as well as the following resources are hypervisor resources, accessible to software only when the thread is in hypervisor state except as noted below.

- All implementation-specific resources except for privileged non-hypervisor implementation-specific SPRs. (See Section 5.4.4 for the list of the implementation-specific SPRs that are allowed to be privileged non-hypervisor SPRs.) Implementation-specific registers include registers (e.g., “HID” registers) that control hardware functions or affect the results of instruction execution. Examples include resources that disable caches, disable hardware error detection, set breakpoints, control power management, or significantly affect performance.

- ME bit of the MSR

- SPRs defined as hypervisor-privileged in Section 5.4.4. (Note: Although the Time Base, the PURR, and the SPURR can be altered only by a hypervisor program, the Time Base can be read by all programs and the PURR and SPURR can be read when the thread is in privileged state.)

The contents of a hypervisor resource can be modified by the execution of an instruction (e.g., `mtspr`) only in hypervisor state (MSR\textsubscript{HV \text{PR}} = 0b10). An attempt to modify the contents of a given hypervisor resource, other than MSR\textsubscript{ME}, in privileged but non-hypervisor state (MSR\textsubscript{HV \text{PR}} = 0b00) causes a Privileged Instruction type Program Interrupt when LPCR\textsubscript{EVIRT}=0 and a Privileged Instruction type Program Interrupt when LPCR\textsubscript{EVIRT}=0 and a

Table 3: Instructions controlled by the v2.07 bit (Sheet 5 of 6)
Hypervisor Emulation Assistance interrupt when LPCREVIRT=1. An attempt to modify MSRME in privileged but non-hypervisor state is ignored (i.e., the bit is not changed).

--- Programming Note ---
Because the SPRs listed above are privileged for writing, an attempt to modify the contents of any of these SPRs in problem state (MSRPR=1) using mtspr causes a Privileged Instruction type Program exception, and similarly for MSRME.

### 2.7 Sharing Hypervisor and Ultravisor Resources

Shared SPRs are SPRs that are accessible to multiple threads. Changes to shared SPRs made by one thread are immediately readable (using mfspr) by all other threads sharing the SPR.

The LPIDR and DPDES must appear to software to be shared among threads of a sub-processor (see Section 2.8). If the implementation does not support sub-processors, the LPIDR and DPDES must be shared among all threads of the multi-threaded processor.

Certain additional hypervisor and ultravisor resources, and the PVR, may be shared among threads. Programs that modify these resources must be aware of this sharing, and must allow for the fact that changes to these resources may affect more than one thread.

The following additional resources may be shared among threads.
- HRMOR (see Section 2.3)
- LPIDR (see Section 2.4)
- PCR (see Section 2.5)
- URMOR (see Section 3.2)
- PVR (see Section 5.3.1)
- RPR (see Section 5.3.7)
- PTCR (see Section 6.7.6.1)
- AMOR (see Section 6.7.13.1)
- HMEER (see Section 7.2.11)
- Time Base (see Section 8.2)
- Virtual Time Base (see Section 8.3)
- Hypervisor Decrementer (see Section 8.5)
- certain implementation-specific registers or implementation-specific fields in architected registers

The set of resources that are shared is implementation-dependent.

Threads that share any of the resources listed above, with the exception of the PTCR, the PVR, the URMOR, and the HRMOR, must be in the same partition.

For each field of the LPCR, except the AIL, EVIRT, ONL, HDICE, MER, PECE, HEIC, and HVICE fields, software must ensure that the contents of the field are identical among all threads that are in the same partition and are not in hypervisor state.

Software must ensure that the contents of UILE and SMFCTRLE are identical among all threads in the system that have completed ultravisor initialization. The contents of the D and UDEE fields of SMFCTRL may differ among threads.

### 2.8 Sub-Processors

Hardware is allowed to sub-divide a multi-threaded processor into "sub-processors" that appear to privileged programs as multi-threaded processors with fewer threads. Such a multi-threaded processor appears to the hypervisor as a processor with a number of threads equal to the sum of all sub-processor threads, and in which the LPIDR for each sub-processor must appear to be shared among all threads of that sub-processor.

### 2.9 Thread Identification Register (TIR)

The TIR is a 64-bit read-only register that contains the thread number, which is a binary number corresponding to the thread.

For implementations that do not support sub-processors, the thread number of a thread is unique among all thread numbers of threads on the multi-threaded processor.

For implementations that support sub-processors, the value of this register depends on whether it is read in hypervisor or privileged, non-hypervisor state as follows.

- When this register is read in privileged, non-hypervisor state, the thread number is unique among all thread numbers of threads on the sub-processor.
- When this register is read in hypervisor state, the thread number is unique among all thread numbers of threads on the multi-threaded processor.

Threads are numbered sequentially, with valid values ranging from 0 to t-1, where t is the number of threads implemented. A thread for which TIR = n is referred to as "thread n."

The layout of the TIR is shown below.

<table>
<thead>
<tr>
<th>TIR</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
</tr>
<tr>
<td>63</td>
</tr>
</tbody>
</table>

--- Figure 4. Thread Identification Register ---
Access to the TIR is privileged.
Since the thread number contained in this register is different if it is read in hypervisor state from when it is read in privileged, non-hypervisor state in implementations that support sub-processors, the following conventions are used.

- The value returned in privileged, non-hypervisor state is referred to as the “privileged thread number.”
- The value returned in hypervisor state is referred to as the “hypervisor thread number.”

### 2.10 Hypervisor Interrupt Little-Endian (HILE) Bit

The Hypervisor Interrupt Little-Endian (HILE) bit is a bit in an implementation-dependent register or similar mechanism. The contents of the HILE bit are copied into MSRLE by interrupts that result in MSR$_{HV}$ being equal to 0b01 (see Section 7.5), to establish the Endian mode for the interrupt handler. The HILE bit is set, by an implementation-dependent method, only during system initialization.

The contents of the HILE bit must be the same for all threads under the control of a given instance of the hypervisor; otherwise all results are undefined.
Chapter 3. Ultravisor and Secure Memory Facility (SMF)

3.1 Overview

The Secure Memory Facility (SMF) provides secure isolation of partitions from one another and from higher privilege system software. SMF functionality is implemented using a combination of hardware facilities and firmware that runs at a privilege level above the hypervisor. SMF targets a threat model in which the hypervisor can be compromised such that its inherent isolation capabilities can no longer be counted on. Maintaining the security of data is the sole objective of the ultravisor. It has no role in platform management and is not expected to deal with denial of service attacks. References elsewhere in the Books to “secure systems” apply more generally, and do not necessarily imply that the system uses SMF.

The SMF protection mechanism is based on the assignment of partitions to security domains. The hypervisor is in one security domain, along with all processes that run directly under the hypervisor and all partitions that do not take advantage of the SMF security capabilities. Each of the secure partitions is assigned to its own security domain so that its data and instructions can be protected from access by other security domains. A partition is identified as secure when MSRS=1. Each location in main storage has an associated Secure Memory property, memSM. Memory with memSM=1 may be referred to as “secure memory.” Memory with memSM=0 may be referred to as “ordinary memory.” The granularity and method with which main storage is mapped for the Secure Memory property is implementation specific. The Secure Memory property is commonly cached in the TLB and in implementation-specific looksaside buffers. When secure data are to be shared with untrusted software, the standard synchronization associated with PTE updates is used to regulate access. For example, prior to sharing secure data, the PTEs used to access the data are marked invalid and the corresponding TLB entries invalidated by the ultravisor using the standard invalidation sequence. (See Section 6.10.1.2.) The data are then encrypted and made available in ordinary memory (either memSM is turned off or the data are moved to ordinary memory). Finally the PTEs that will be used to access the data in ordinary memory are marked valid. (The last step may be done lazily.) Software running with MSR_S=0 is prohibited from accessing secure memory. Software running with MSR_S=1 may access both secure and ordinary memory.

SMF firmware runs in ultravisor state, a privilege level above that of the hypervisor. That firmware, along with the SMF hardware, is responsible for maintaining isolation of secure partitions from each other and from the hypervisor. This is accomplished by direct ultravisor management of the partition-scoped translation tables in secure memory for secure partitions. The ultravisor itself runs only in (ultravisor) real addressing mode. Security is the result of proper management of the partition-scoped translation together with the hardware enforcement of the access restriction for secure memory. With this hybrid approach, firmware has the ability to enable secure memory sharing between secure partitions and ordinary memory sharing between a given secure partition and the hypervisor, e.g. for system calls. The ultravisor can access any architecture resource or facility.

The hypervisor is expected to cooperate in the management of secure partitions by using ultravisor calls to dispatch them and to manage their storage allocations. To protect against programming errors and malicious hypervisor behavior, mtmsr[d], rfid, hrfd, and rtscv preserve MSR_S and hypervisor interrupts from secure partitions are always received in ultravisor state.

The purpose of intercepting hypervisor interrupts is to protect the state of the secure partition from the hypervisor. The ultravisor’s interrupt handler provides a ‘shim’ that saves and clears the processing state, and then transfers control to the hypervisor to handle the exception condition itself. The ultravisor will restore the secure partition state when it services the ultravisor call to (re-) dispatch the secure partition. Note that the ultravisor’s goal is merely to protect the security of
data, and not to provide broader system management oversight.

### 3.2 Ultravisor Real Mode Offset Register (URMOR)

The layout of the Ultravisor Real Mode Offset Register (URMOR) is shown in Figure 5 below.

**Figure 5. Ultravisor Real Mode Offset Register**

All other fields are reserved.

The supported URMO values are the non-negative multiples of $2^r$, where $r$ is the same implementation-dependent value that constrains the HRMO field of the HRMOR.

The contents of the URMOR affect how some storage accesses are performed as described in Sections 6.7.3 and 6.7.5.

### 3.3 Ultravisor Interrupt Little-Endian (UILE) Bit

The Ultravisor Interrupt Little-Endian (UILE) bit is a bit in an implementation-dependent register or similar mechanism. The contents of the UILE bit are copied into SMSCF by interrupts that result in MSR_S_HV being equal to 0b11 (see Section 7.5), to establish the Endian mode for the interrupt handler. The UILE bit is set, by an implementation-dependent method, only during system initialization.

The contents of the UILE bit must be the same for all threads in the system; otherwise all results are undefined.

### 3.4 Secure Memory Facility Control Register (SMFCTRL)

The Secure Memory Facility Control Register (SMFCTRL) is shown in Figure 6 below.

**Figure 6. Secure Memory Facility Control Register (SMFCTRL)**

If SMFCTRL_E=0, SMFCTRL_D and SMFCTRL_UDEE must be set to zero. References to SMFCTRL_D=1 or SMFCTRL_UDEE=1 elsewhere in the architecture assume SMFCTRL_E=1 unless otherwise stated or obvious from context.
3.4.1 Enabling SMF and Secure Memory Enforcement

The SMFCTRL_E bit enables SMF functionality. When SMFCTRL_E=1, certain facilities are ultravisor resources instead of hypervisor resources and secure memory checking is enabled.

Independent of the basic feature enablement above, SMF has state transition rules that facilitate the protection of security domains. (While these rules are nominally independent of the value of SMFCTRL_E, some transitions cannot happen when SMFCTRL_E=0. Specifically, ultravisor interrupts cannot occur when SMFCTRL_E=0.)

- All interrupts that are not ultravisor interrupts preserve MSR_S. (Ultravisor interrupts necessarily set MSR_S to 1.)
- mtmsr[d], rfid, hrfid, and rfscv are not permitted to change MSR_S.

Table 4 summarizes the effect of the SMFCTRL_E bit and the MSR_S.HV.PR bits on various facilities.

dc = don't care
** The encoding MSR<sub>S</sub> HV/PR=0b111 is reserved and must not be used.

Table 4: Ultravisor Resource Behavior

---

**Programming Note**

Access to memory by mechanisms outside the core must also enforce secure memory access restrictions. Facilities that translate addresses or otherwise use real addresses to access memory must check mem<sub>SM</sub> against PATE<sub>S</sub> for the partition on behalf of which they access memory.

Such mechanisms will require a means to evaluate mem<sub>SM</sub> and a proxy for SMFCTRL<sub>E</sub> to provide the same enablement function for secure memory access enforcement as in the core.

In addition or as an alternative, TCE tables may be managed by the ultravisor and used to identify regions of memory that I/O devices may access.
Chapter 4. Branch Facility

4.1 Branch Facility Overview

This chapter describes the details concerning the registers and the privileged instructions implemented in the Branch Facility that are not covered in Book I.

4.2 Branch Facility Registers

4.2.1 Machine State Register

The Machine State Register (MSR) is a 64-bit register. This register defines the state of the thread. On interrupt, the MSR bits are altered in accordance with Figure 67 on page 1261. The MSR can also be modified by the \texttt{mtmsr[d]}, \texttt{rfscv}, \texttt{rfid}, \texttt{hrfid}, and \texttt{urfid} instructions. It can be read by the \texttt{mfmsr} instruction.

**Figure 7. Machine State Register**

Below are shown the bit definitions for the Machine State Register.

<table>
<thead>

</tr>
<tr>
<td>1</td>
<td>If MSR\textsubscript{PR}=0, the thread is in hypervisor state; otherwise the thread is not in hypervisor state.</td>
</tr>
</tbody>
</table>

**Programming Note**

The privilege state of the thread is determined by MSR\textsubscript{S}, MSR\textsubscript{HV}, and MSR\textsubscript{PR}, as follows.

<table>
<thead>
<tr>
<th>S</th>
<th>HV</th>
<th>PR</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>x</td>
<td>1</td>
<td>problem</td>
</tr>
<tr>

<tr>
<td>1</td>
<td>1</td>
<td>0</td>
<td>ultravisor</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
<td>1</td>
<td>reserved</td>
</tr>
</tbody>
</table>

Hypervisor state is also a privileged state (MSR\textsubscript{PR} = 0). All references to “privileged state” in the Books include hypervisor state unless otherwise stated or obvious from context. Ultravisor state is also a hypervisor state (MSR\textsubscript{HV} PR = 0b10). All references to “hypervisor state” in the Books include ultravisor state unless otherwise stated or obvious from context.

MSR\textsubscript{HV} can be set to 1 only by the \texttt{System Call} instruction and some interrupts. It can be set to 0 only by \texttt{rfid}, \texttt{hrfid}, and \texttt{urfid}.

It is possible to run an operating system in an environment that lacks a hypervisor, by always having MSR\textsubscript{HV} = 1 and using MSR\textsubscript{HV} PR = 0b10 for the operating system (effectively, the OS runs in hypervisor state) and MSR\textsubscript{HV} PR = 0b11 for applications. In this use, MSR\textsubscript{S} would be 0, and the environment would also lack an ultravisor.

Reserved

Software must ensure that this bit contains 0; otherwise the results of executing all instructions are boundedly undefined.
This bit is initialized to 0 by hardware at system bringup. The handling of this bit by interrupts and by the `rfid`, `hrfid`, `urfid`, and `rsfscv` instructions is such that, unless software deliberately sets the bit to 1, the bit will continue to contain 0.

### Vector Available (VEC)

0 The thread cannot execute any vector instructions, including vector loads, stores, and moves.
1 The thread can execute vector instructions unless they have been made unavailable by some other register.

### Problem State (PR)

0 The thread is in privileged state.
1 If MSR$_{HVPR} = 0b11$, the thread is in problem state.

### Programming Note

An application binary interface defined to support Vector-Scalar operations should also specify a requirement that MSR$_{FP}$ and MSR$_{VEC}$ be set to 1 whenever MSR$_{VSX}$ is set to 1.

### Secure (S)

0 The thread is not in Secure state. It may not access Secure memory. The thread is not in ultravisor state.
1 The thread is in Secure state. If MSR$_{HV}=1$ and MSR$_{PR}=0$, the thread is in ultravisor state; otherwise the value does not affect privilege. The state with MSR$_{HV}=1$ and MSR$_{PR}=1$ is reserved. Software must not set MSR$_{HVPR} = 0b111$. References elsewhere in this document to MSR$_{HVPR}=0b11$ assume MSR$_{S}=0$ unless otherwise stated or obvious from context.

### Machine Check Interrupt Enable (ME)

0 Machine Check interrupts are disabled.
1 Machine Check interrupts are enabled.

This bit is a hypervisor resource; see Chapter 2, “Logical Partitioning (LPAR) and Thread Control”, on page 1121.

### Programming Note

The only instructions that can alter MSR$_{ME}$ are `rfid`, `hrfid`, and `urfid`.

### Floating-Point Available (FP)

0 The thread cannot execute any floating-point instructions, including floating-point loads, stores, and moves.
1 The thread can execute floating-point instructions unless they have been made unavailable by some other register.

### Programming Note

Any instruction that sets MSR$_{PR}$ to 1 also sets MSR$_{EE}$, MSR$_{IR}$, and MSR$_{DR}$ to 1.

The state with MSR$_{HVPR} = 0b111$ is reserved.

### Floating-Point Exception Mode 0 (FE0)

See below.

### Trace Enable (TE)

00 Trace Disabled: The thread executes instructions normally.
01 Branch Trace: The thread generates a Branch type Trace interrupt after completing the execution of a branch instruction, whether or not the branch is taken.

10 Single Step Trace: The thread generates a Single-Step type Trace interrupt after successfully completing the execution of the next instruction, unless that instruction is a \textit{urfid}, \textit{hrfid}, \textit{rfid}, \textit{rfscv}, or a Power-Saving Mode instruction, all of which are never traced. Successful completion means that the instruction caused no other interrupt.

11 Reserved.

Branch tracing need not be supported. If the function is not implemented, the 0b01 bit encoding is treated as reserved.

55 \textbf{Floating-Point Exception Mode 1 (FE1)}

See below.

56:57 Reserved

58 \textbf{Instruction Relocate (IR)}

0 Instruction address translation is disabled.
1 Instruction address translation is enabled.

\textbf{Programming Note}

See the Programming Note in the definition of MSR\textsubscript{S} and in the definition of MSR\textsubscript{PR}.

59 \textbf{Data Relocate (DR)}

0 Data address translation is disabled. Effective Address Overflow (EAO) (see Book I) does not occur.
1 Data address translation is enabled. EAO causes a Data Storage interrupt.

60 Reserved

61 \textbf{Performance Monitor Mark (PMM)}

This bit is used by software in conjunction with the Performance Monitor, as described in Chapter 10.

Before hypervisor support was added to the architecture, “translation is disabled” for MSR\textsubscript{IR}=0 truly meant that no translation was performed for instruction addresses, and correspondingly for MSR\textsubscript{DR}=0 for data addresses. The architecture continues to use “translation is disabled” to refer to MSR\textsubscript{IR}=0 and MSR\textsubscript{DR}=0 despite that the behavior today is more complicated. When MSR\textsubscript{HV IR}=0b10, it is still true that no translation is performed for instruction addresses, and correspondingly for data addresses if MSR\textsubscript{HV DR}=0b10. But in privileged non-hypervisor state when MSR\textsubscript{IR}=0 or MSR\textsubscript{DR}=0, limited translation is performed under control of the hypervisor. For an HPT translation guest, translation is performed as described in Section 6.7.3.3, with storage exceptions directed to the hypervisor. For a Radix Tree Translation guest, only partition-scoped translation is performed, with storage exceptions directed to the hypervisor.
0 The thread is in Big-Endian mode.
1 The thread is in Little-Endian mode.

Programming Note

The only instructions that can alter MSR LE are rfd, hrdid, urfd, and rfscv.

The Floating-Point Exception Mode bits FE0 and FE1 are interpreted as shown below. For further details see Book I.

<table>
<thead>
<tr>
<th>FE0</th>
<th>FE1</th>

<td>Imprecise Recoverable</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
<td>Precise</td>
</tr>
</tbody>
</table>

Recoverable Interrupt (RI)

0 Interrupt is not recoverable.
1 Interrupt is recoverable.

Additional information about the use of this bit is given in Sections 7.4.3, “Interrupt Processing” on page 1256, 7.5.1, “System Reset Interrupt” on page 1262, and 7.5.2, “Machine Check Interrupt” on page 1264.

Little-Endian Mode (LE)

Common uses of the PMM bit include the following.

- All counters count events for a few selected processes. This use requires the following bit settings:
  - MSR\textsubscript{PMM} = 1 for the selected processes, MSR\textsubscript{PMM} = 0 for all other processes
  - MMCR\textsubscript{FCM0} = 1
  - MMCR\textsubscript{FCM1} = 0
  - MMCR2 = 0x0000

- All counters count events for all but a few selected processes. This use requires the following bit settings:
  - MSR\textsubscript{PMM} = 1 for the selected processes, MSR\textsubscript{PMM} = 0 for all other processes
  - MMCR\textsubscript{FCM0} = 0
  - MMCR\textsubscript{FCM1} = 1
  - MMCR2 = 0x0000

Notice that for both of these uses a mark value of 1 identifies the “few” processes and a mark value of 0 identifies the remaining “many” processes. Because the PMM bit is set to 0 when an interrupt occurs (see Figure 67 on page 1261), interrupt handlers are treated as one of the “many”. If it is desired to treat interrupt handlers as one of the “few”, the mark value convention just described would be reversed.

If only a specific counter n is to be frozen, MMCR\textsubscript{FCM0} FCM\textsubscript{1} is set to 0b00, and MMCR\textsubscript{FCM0} FCM\textsubscript{1} instead of MMCR\textsubscript{FCM0} FCM\textsubscript{1} and MMCR\textsubscript{FCM1} FCM\textsubscript{1} are set to the values described above.
4.2.2 Processor Stop Status and Control Register (PSSCR)

The layout of the PSSCR is shown below.

```
|   PLS |   /   /   |   0  |  4  |  8  | 12  | 16  | 20  | 24  | 28  | 32  | 36  | 40  | 44  | 48  | 52  | 56  | 60  |
|-------|----------|------|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|
```

**Figure 8. Processor stop Status and Control Register**

The contents of the PSSCR control the operation of the `stop` instruction and provide status indicating the level of power saving that was entered while in power-saving mode.

All fields of this register can be read and written by the hypervisor using either hypervisor SPR 855 or privileged SPR 823. A subset of the fields of this register can be read and written in privileged non-hypervisor state using privileged SPR 823, as specified below. Fields that can only be read or written by the hypervisor are indicated below; all other fields can be read or written in either privileged non-hypervisor or hypervisor states. When a field that is accessible only to the hypervisor is accessed in privileged non-hypervisor state, writes have no effect and reads return 0s regardless of the value of the field.

The bits and their meanings are as follows.

- **0:3 Power-Saving Level Status (PLS)**
  
  Hardware sets this field to the highest power-saving level that the thread entered between the time when the `stop` instruction is executed and when the thread exits power-saving mode. See the description of the SD field for the value returned in this field when the PSSCR is read.

  **Programming Note**

  Since the power-saving level entered during power-saving mode may vary with time, the PLS field may not indicate the power-saving level that existed at exit from power-saving mode.

- **4:40 Reserved**

- **41 Status Disable (SD)**

  This field is accessible only to the hypervisor.

  0 The current value of the PLS field is returned in the PLS field when reading the PSSCR (using `mfspr`).

  1 0’s are returned in the PLS field when reading the PSSCR (using `mfspr`).

  ```
  Programming Note
  ```

  Exception if SMFCTRLUDEE was set to 0 when

  ```

  **Enable State Loss (ESL)**

  This field is accessible only to the hypervisor.

  0 State loss while in power-saving mode is controlled by the RL, MTL, and PSLL fields.

  1 Non-hypervisor state loss is allowed while in power-saving mode in addition to state loss controlled by the RL, MTL, and PSLL fields.

  If this field is set to 1 when the `stop` instruction is executed in privileged non-hypervisor state, a Hypervisor Facility Unavailable interrupt occurs. See Section 7.5.26.

  For power-saving levels that allow loss of the LPCR, implementations must provide the means to exit power-saving mode upon the occurrence of a System Reset exception and any of the exceptions that were enabled by the PECE field when the `stop` instruction was executed. For this case, the implementation is also allowed to exit on the occurrence of any exceptions that were disabled by the PECE as well.

  For power-saving levels that allow loss of SMFCTRL, implementations must provide the means to exit power-saving mode upon the occurrence of a Directed Ultravisor Doorbell exception if SMFCTRLUDEE was set to 1 when `stop` was executed. For this case, the implementation is also allowed to exit on the occurrence of a Directed Ultravisor Doorbell `stop` was executed.
Exit Criterion (EC)

This field is accessible only to the hypervisor.

0 Hardware will exit power-saving mode when the exception corresponding to any system-caused interrupt occurs. Power-saving mode is exited either at the instruction following the stop (if MSR_{EE}=0) or in the corresponding interrupt handler (if MSR_{EE}=1).

1 If SMFCtrl_{UDED} was set to 1 when stop was executed and SMFCtrl_{UDED} was not lost, hardware will exit power-saving mode when a Directed Ultravisor Doorbell exception occurs. If LPCR_{PECE} is not lost, hardware will exit power-saving mode when a System Reset exception or one of the events specified in LPCR_{PECE} occurs. If the event is a Machine Check exception, then a Machine Check interrupt occurs; otherwise a System Reset interrupt occurs, and the contents of SRR1 indicate the event that caused exit from power-saving mode.

When the stop instruction is executed in hypervisor state, the hypervisor must set the ESL field to the same value as this field. Also, if the RL or MTL fields are set to values that allow state loss, then fields ESL and EC must both be set to 1. Other combinations of the values of the ESL, EC, RL, and MTL fields are reserved for future use.

Power-Saving Level Limit (PSLL)

This field is accessible only to the hypervisor.

This field limits the power-saving level that may be entered or transitioned into when the stop instruction is executed in privileged non-hypervisor state; when the stop instruction is executed in hypervisor state, this field is ignored.

Transition Rate (TR)

This field is used to specify the relative rate at which the power-saving level increases during power-saving mode. The rate of power-saving level increase corresponding to each value is implementation-dependent, and monotonically increasing with the value specified.

Maximum Transition Level (MTL)

If the value of this field is greater than the value of the Power-Saving Level Limit (PSLL) field when stop is executed in privileged non-hypervisor state, a Hypervisor Facility Unavailable interrupt occurs. See Section 7.5.26 of Book III.

Otherwise, if the value of this field is greater than the value of the RL field, the power-saving level is allowed to increase from the value in the RL field up to the value of this field during power-saving mode.

If this field is less than or equal to the value of the PSLL field when stop is executed in privileged non-hypervisor state, this field is used to specify the maximum power-saving level that can be reached during power-saving mode provided that the value of this field is greater than the value of the RL field. If this field is less than the Requested Level (RL) field when stop is executed hardware is not allowed to increase the power-saving level beyond the value indicated in the RL field.

Requested Level (RL)

When state loss occurs, thread resources such as SPRs, GPRs, address translation resources, etc. may be powered off or allocated to other threads during power-saving mode. The amount of state loss for various combinations of ESL, RL, and MTL values is implementation dependent, subject to the restrictions specified in Section 4.3.2.

In order to enable an OS to enter power-saving mode without hypervisor involvement, both the EC and ESL bits must be set to 0s. When this is done, OS execution of the stop instruction will not cause hypervisor involvement provided that bits RL and MTL are less than or equal to PSLL. See Section 7.5.26 for details.

Programming Note

In order to enable an OS to enter power-saving mode without hypervisor involvement, both the EC and ESL bits must be set to 0s. When this is done, OS execution of the stop instruction will not cause hypervisor involvement provided that bits RL and MTL are less than or equal to PSLL. See Section 7.5.26 for details.

Programming Note

If the event is a Machine Check exception, then a Machine Check interrupt occurs; otherwise a System Reset interrupt occurs, and the contents of SRR1 indicate the event that caused exit from power-saving mode.

When the stop instruction is executed in hypervisor state, the hypervisor must set the ESL field to the same value as this field. Also, if the RL or MTL fields are set to values that allow state loss, then fields ESL and EC must both be set to 1. Other combinations of the values of the ESL, EC, RL, and MTL fields are reserved for future use.

Other combinations of the values of the ESL, EC, RL, and MTL fields may be allowed in a future version of the architecture in order to provide additional functionality.

If this field is set to 1 when the stop instruction is executed in privileged non-hypervisor state, a Hypervisor Facility Unavailable interrupt occurs. See Section 7.5.26.
This field is used to specify the power-saving level that is to be entered when the `stop` instruction is executed.

If the value of this field is greater than the value of the Power-Saving Level Limit (PSLL) field when `stop` is executed in privileged non-hypervisor state, a Hypervisor Facility Unavailable interrupt occurs.

---

**Programming Note**

The Hypervisor Facility Unavailable interrupt occurs when a privileged non-hypervisor program executes `stop` when PSSCR<sub>RL</sub> > PSSCR<sub>PSLL</sub> so that the Hypervisor may decide whether or not to allow the requested loss of state to occur.

If the hypervisor decides that some loss of state is acceptable, it may choose to re-execute `stop` after either setting PSSCR<sub>MTL</sub> to a value that causes state loss, or setting both PSSCR<sub>RL</sub> and PSSCR<sub>MTL</sub> to values that cause state loss. When the thread exits power-saving mode, the hypervisor can quickly determine whether any resources were actually lost and need to be restored.
4.3 Branch Facility Instructions

4.3.1 System Linkage Instructions

These instructions provide the means by which a program can call upon the system to perform a service, and by which the system can return from performing a service or from processing an interrupt.

The System Call instruction is described in Book I, but only at the level required by an application programmer. A complete description of this instruction appears below.

**System Call**

**SC-form**

```
    sc    LEV
```

<table>
<thead>
<tr>
<th></th>
<th>0</th>
<th>6</th>
<th>11</th>
<th>16</th>
<th>20</th>
<th>27</th>
<th>30</th>
<th>31</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>17</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

SRR0 ← lea CIA + 4
SRR1[33:36 42:47] ← 0
MSR ← new value (see below)
NIA ← 0x0000_0000_0000_0C00

The effective address of the instruction following the System Call instruction is placed into SRR0. Bits 0:32, 37:41, and 48:63 of the MSR are placed into the corresponding bits of SRR1, and bits 33:36 and 42:47 of SRR1 are set to zero.

Then a System Call interrupt is generated. The interrupt causes the MSR to be set as described in Section 7.5, "Interrupt Definitions" on page 1260. The setting of the MSR is affected by the contents of the LEV field. LEV values greater than 2 are reserved. Bits 0:4 of the LEV field (instruction bits 20:24) are treated as a reserved field.

The interrupt causes the next instruction to be fetched from effective address 0x0000_0000_0000_0C00.

This instruction is context synchronizing.

**Special Registers Altered:**

SRR0  SRR1  MSR

--- Programming Note

If LEV=1, the hypervisor is invoked.

If LEV=2 and SMFCTRL_E = 1, the ultravisor is invoked.

If LEV=2 and SMFCTRL_E = 0, the hypervisor is invoked. However, such invocation should be considered a programming error.

Executing this instruction with LEV=1 or LEV=2 is the only way that executing an instruction can cause a transition from non-hypervisor state to hypervisor state on the thread that executed the instruction. Executing this instruction with LEV=2 when SMFCTRL_E=1 is the only way that executing an instruction can cause a transition from non-ultravisor state to ultravisor state on the thread that executed the instruction.

In correct use, this instruction is used to "call up" one privilege level (application program calls operating system, operating system calls hypervisor, hypervisor calls ultravisor). However, it is possible for a program to call up more than one level (e.g., for an application program to call the hypervisor). An attempt to call up more than one level should be considered a programming error.

--- Programming Note

**sc** serves as both a basic and an extended mnemonic. The Assembler will recognize an **sc** mnemonic with one operand as the basic form, and an **sc** mnemonic with no operand as the extended form. In the extended form the LEV operand is omitted and assumed to be 0.
**System Call Vectored SC-form**

```
scv         LEV

- `MSR` ← new_value (see below)
- `NIA` ← (see below)

The effective address of the instruction following the `System Call Vectored` instruction is placed into the Link Register. Bits 0:32, 37:41, and 48:63 of the MSR are placed into the corresponding bits of Count Register, and bits 33:36 and 42:47 of Count Register are set to undefined values.

Then a System Call Vectored interrupt is generated. The interrupt causes the MSR to be altered as described in Section 7.5.

The interrupt causes the next instruction to be fetched as specified in LPCR_{AIL} or LPCR_{HAIL} as appropriate (see Section 2.2).

The SRRs are not affected.

This instruction is context synchronizing.

**Special Registers Altered:**

- LR
- CTR
- MSR

**Return From System Call Vectored XL-form**

The result of ORing bits 48 and 49 of the Count Register is placed into MSR_{48}. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of the Count Register is complemented and then ANDed with the result of ORing bits 58 and 49 of the Count Register and placed into MSR_{58}. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of the Count Register is complemented and then ANDed with the result of ORing bits 58 and 49 of the Count Register and placed into MSR_{58}. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of the Count Register is complemented and then ANDed with the result of ORing bits 58 and 49 of the Count Register and placed into MSR_{58}. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of the Count Register is complemented and then ANDed with the result of ORing bits 58 and 49 of the Count Register and placed into MSR_{58}. If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address LR_{0:61} | 0b00 (when SF=1 in the new MSR value) or LR_{0:61} | 0b00 (when SF=0 in the new MSR value). If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into SRR0, HSRR0, or USRR0 by the interrupt processing mechanism (see Section 7.4.3) is the address of the instruction that would have been executed next had the interrupt not occurred.

This instruction is privileged and context synchronizing.

**Special Registers Altered:**

- MSR

---

**Programming Note**

If this instruction sets MSR_{PR} to 1, it also sets MSR_{EE}, MSR_{IR}, and MSR_{DR} to 1. If this instruction results in MSR_{HV PR} being equal to 0b110, it also sets MSR_{IR} and MSR_{DR} to 0.

This instruction does not alter MSR_{HV}, MSR_{S}, or MSR_{ME}.
Return From Interrupt Doubleword

The result of ORing bits 48 and 49 of USRR1 is placed into MSR48. The result of ANDing bit 41 of USRR1 with bit 3 of USRR1 and with the complement of bit 49 of USRR1 is complemented and then ANDed with the result of ORing bits 58 and 49 of USRR1 and placed into MSR58. The result of ANDing bit 41 of USRR1 with bit 3 of USRR1 and with the complement of bit 49 of USRR1 is complemented and then ANDed with the result of ORing bits 59 and 49 of USRR1 and placed into MSR59. Bits 0:32, 37:41, 49:57, and 60:63 of USRR1 are placed into the corresponding bits of the MSR.

If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address USRR0.61 || 0b00 (when SF=1 in the new MSR value) or 32 || USRR0.32.61 || 0b00 (when SF=0 in the new MSR value). If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into SRR0, HSRR0, or USRR0 by the interrupt processing mechanism (see Section 7.4.3) is the address of the instruction that would have been executed next had the interrupt not occurred.

This instruction is ultravisor privileged and context synchronizing.

Special Registers Altered:
MSR

Programming Note

If this instruction sets MSRPR to 1, it also sets MSREE, MSRIR, and MSDR to 1. If this instruction sets MSRHVPR to 0b110, it also sets MSRIR and MSDR to 0.
4.3.2 Power-Saving Mode

Power-Saving Mode is a mode in which the thread does not execute instructions and may consume less power than it would if it were not in power-saving mode.

There are 16 levels of power savings, designated as levels 0-15. For each power-saving level, the power consumed may be less than or equal to the power consumed in the next-lower level, and the time required for the thread to exit power-saving mode and resume execution may be greater than or equal that of the next-lower level.

When the thread is in power-saving mode, some resource state may be lost. The state that may be lost while in each power-saving level is implementation dependent, with the following restrictions.

- For PSSCRESL = 0 and power-saving level 0000, no thread state is lost.
- There must be a power-saving level in which the Decrementer and all hypervisor resources are maintained as if the thread was not in power-saving mode, and in which sufficient information is maintained to allow the hypervisor to resume execution.
- The amount of state loss in a given level is less than or equal to the amount of state loss in the next higher level.
- The state of all read-only resources, SMFCTRL\_E, and the URMOR in an SMF-enabled system or the HRMOR in an SMF-disabled system is always maintained.

**Programming Note**

For the power-saving level corresponding to the second item above, if the state of the Decrementer were not maintained and updated as if the thread was not in power-saving mode, Decrementer exceptions would not reliably cause exit from this power-saving level even if Decrementer exceptions were enabled to cause exit.
4.3.2.1 Power-Saving Mode Instruction

The **stop** instruction is used to stop instruction fetching and execution and put the thread into power-saving mode. The thread remains in power-saving mode until a system reset exception or an event that is enabled to cause exit from power-saving mode occurs. (See the definition of PSSCREC in Section 4.2.2.)

### stop  Xl-form

```
stop
```

The thread is placed into power-saving mode and execution is stopped.

The power-saving level that is entered is determined by the contents of the PSSCR (see Section 4.2.2). The thread state that is maintained depends on the power-saving level that is entered. The thread state that is maintained at each power-saving level is implementation-dependent, subject to the restrictions specified in Section 4.3.2. If MSREE=0 or in the corresponding interrupt handler (if MSREE=1).

If MSREE=1 when the **stop** instruction is executed, then the interrupt corresponding to the exception that was expected to cause exit from power-saving mode may occur immediately prior to execution of the **stop** instruction. If this occurs, the result may be a software hang condition since the exception that was expected to cause exit from power-saving mode has already occurred.

The above software hang condition can be prevented by setting MSR_EE=0 prior to executing **stop**.

After the thread has entered power-saving mode with PSSCREC=0, any exception may cause exit from power-saving mode. When an exception occurs, power-saving mode is exited either at the instruction following the **stop** (if MSREE=0) or in the corresponding interrupt handler (if MSREE=1).

### Programming Note

If **stop** was executed when PSSCREC=0, then PSSCRESL must also be set to 0 and PSSCREL must be set to values that do not allow state loss. (See the definition of the EC bit description in Section 4.3.2.) This guarantees that the state of MSREE is not lost.

### Special Registers Altered:
None

4.3.2.2 Entering and Exiting Power-Saving Mode

Before software executes the **stop** instruction, the PSSCR is initialized. If the **stop** instruction is to be used by the OS, the hypervisor initializes the fields that are accessible only to the hypervisor before dispatching the OS. These fields include the SD, ESL, EC, and PSLL fields. See the Programming Notes for these fields in Section 4.2.2 for additional information.

If the **stop** instruction is to be executed by the hypervisor when PSSCREC=1, LPCR_PEC and SMFCTR_LUDEE must be set to the desired value (see Sections 2.2 and 3.4). Depending on the implementation and the power-saving level to be entered, it may also be necessary to save the state of certain resources and perform synchronization procedures to ensure that all stores have been performed with respect to other threads or mechanisms that use the storage areas before executing the **stop**. See the the User’s Manual for the implementation for details.

Software must also specify the requested and maximum power-saving level limit fields (i.e RL and MTL fields), and the Transition Rate (TR) field in the PSSCR in order to bound the range of power-saving modes that can be entered. If the value of the RL field is greater than or equal to the value of the MTL field, the power-saving level will not increase from the initial level during power-saving mode.

### Programming Note

If MSR_EE=1 when the **stop** instruction is executed, then the interrupt corresponding to the exception that was expected to cause exit from power-saving mode may occur immediately prior to execution of the **stop** instruction. If this occurs, the result may be a software hang condition since the exception that was expected to cause exit from power-saving mode has already occurred.

The above software hang condition can be prevented by setting MSR_EE=0 prior to executing **stop**.
After the thread has entered power-saving mode with PSSCR EC=1, only the System Reset exception and the exceptions enabled in LPCR PECE and SMFCTRL UDEE will cause exit. If the event that causes exit is a Machine Check exception, then a Machine Check interrupt occurs; otherwise a System Reset interrupt occurs, and the contents of SRR1 indicate the exception that caused exit from power-saving mode. If state loss has occurred in an SMF-enabled system, the interrupt is taken in ultravisor state.

If the hypervisor has set PSSCR SD=0 prior to when the stop instruction is executed, the instruction following the stop may typically be a mfspr in order to read the contents of PSSCR PLS to determine the maximum power-saving level that was entered during power-saving mode.

--- Programming Note ---

If stop was executed when PSSCR EC=0 and MSR CE=0 (in order to avoid the hang condition described in a preceding Programming Note), MSR CE should be set to 1 after power-saving mode is exited in order to take the interrupt corresponding to the exception that caused exit from power-saving mode.

If stop was executed when PSSCR EC=0 and MSREE=0 (in order to avoid the hang condition described in a preceding Programming Note), MSREE should be set to 1 after power-saving mode is exited in order to take the interrupt corresponding to the exception that caused exit from power-saving mode.

--- Programming Note ---

The ultravisor does not initiate power-saving.

If a secure partition attempts to execute stop with parameters that allow state loss, the ultravisor gets control via the Hypervisor Facility Unavailable interrupt. It saves secure state and gives control to the hypervisor’s Hypervisor Facility Unavailable interrupt handler.

Upon exit from a state-losing power-saving mode in an SMF-enabled system, the ultravisor gets control at its Machine Check or System Reset interrupt handler. It restores any ultravisor state that was lost, and then services the Directed Ultravisor Doorbell exception if that caused the wakeup. It then restores the HRMOR and transfers control to the hypervisor’s Machine Check interrupt handler if the ultravisor got control at the ultravisor’s Machine Check interrupt handler, and to the hypervisor’s System Reset interrupt handler otherwise. The hypervisor restores any lost hypervisor state, and then handles the exception (other than Directed Ultravisor Doorbell exception) that caused the wakeup. For this process to work, the ultravisor must have stored a record of its state in some known location prior to transferring control to the hypervisor to execute stop. The hypervisor in turn must have stored its HRMOR value in a location known to the ultravisor. It must also have stored a record of its state in some known location.

The only other function the ultravisor may need to perform for a given power-saving mode transition is to be a proxy accessing hypervisor state in the platform that is mixed with ultravisor state and lacking independent access control.
4.4 Event-Based Branch Facility and Instruction

The Event-Based Branch facility is described in Chapter 6 of Book II, but only at the level required by the application program.

Event-based branches can only occur in problem state and when event-based branches and exceptions have been enabled in the FSCR and HFSCR, and BESCRGE=1. Additionally, the following additional bits must be set to one in order to enable EBB exceptions specific to a given function to occur.

- MMCR0EBE and BESCPME must be set to 1 to enable Performance Monitor event-based exceptions.
- BESCRGE must be set to 1 to enable External event-based exceptions.

If an event-based exception exists (as indicated by BESCRPMEO=1 or BESCREEO=1) when MSRPR=0, the corresponding event-based branch will occur when MSRPR=1, FSCRBB=1, HFSCRBB=1, and BESCRGE=1.

**Programming Note**

Software EBB handlers should ensure that previous exceptions have been cleared (by setting BESCPME0 and/or BESCREEO to 0) before re-enabling event-based branches (by setting BESCRGE to 1 or executing rfebb 1) in order to prevent earlier exceptions from causing additional EBBs.
Chapter 5. Fixed-Point Facility

5.1 Fixed-Point Facility Overview

This chapter describes the details concerning the registers and the privileged instructions implemented in the Fixed-Point Facility that are not covered in Book I.

5.2 Special Purpose Registers

Special Purpose Registers (SPRs) are read and written using the \texttt{mfspr} (page 1173) and \texttt{mtspr} (page 1171) instructions. Most SPRs are defined in other chapters of this book; see the index to locate those definitions.

5.3 Fixed-Point Facility Registers

5.3.1 Processor Version Register

The Processor Version Register (PVR) is a 32-bit read-only register that contains a value identifying the version and revision level of the implementation. The contents of the PVR can be copied to a GPR by the \texttt{mfspr} instruction. Read access to the PVR is privileged; write access is not provided.

![Figure 9. Processor Version Register](image)

The PVR distinguishes between implementations that differ in attributes that may affect software. It contains two fields.

- **Version**: A 16-bit number that identifies the version of the implementation. Different version numbers indicate major differences between implementations.

- **Revision**: A 16-bit number that distinguishes between implementations of the version. Different revision numbers indicate minor differences between implementations having the same version number, such as clock rate and Engineering Change level.

Version numbers are assigned by the Power ISA process. Revision numbers are assigned by an implementation-defined process.

5.3.2 Processor Identification Register

The Processor Identification Register (PIR) is a 32-bit register that contains a 20-bit PROCID field that can be used to distinguish the thread from other threads in the system. The contents of the PIR can be copied to a GPR by the \texttt{mfspr} instruction. Read access to the PIR is privileged; write access is not provided.

![Figure 10. Processor Identification Register](image)

The means by which the PIR is initialized are implementation-dependent.

The PIR is a hypervisor resource; see Chapter 2.

<table>
<thead>
<tr>
<th>Bits</th>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32:43</td>
<td>PROCID</td>
<td>Reserved</td>
</tr>
<tr>
<td>44:63</td>
<td>PROCID</td>
<td>Thread ID</td>
</tr>
</tbody>
</table>

The means by which the PIR is initialized are implementation-dependent.

The PIR is a hypervisor resource; see Chapter 2.
5.3.3 Process Identification Register

The layout of the Process Identification Register (PIDR) is shown in Figure 11 below.

![Figure 11. Process Identification Register](image)

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32:63</td>
<td>PID</td>
<td>Process Identifier</td>
</tr>
</tbody>
</table>

Access to the PIDR is privileged.

**Programming Note**
Radix tree translation assigns special meaning to PID=0, specifically indicating the operating system's kernel process. When GR=1, PIDR should not be set to zero except when MSRPR=0.

5.3.4 Control Register

The Control Register (CTRL) is a 32-bit register as shown below.

![Figure 12. Control Register](image)

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32:47</td>
<td>Reserved</td>
</tr>
<tr>
<td>48:55</td>
<td>Thread State (TS)</td>
</tr>
</tbody>
</table>

- Problem State Access
- Privileged Non-hypervisor State Access
- Hypervisor State Access

The RUN bit can be used by the operating system to indicate when the thread is doing useful work.

Write access to the CTRL is privileged. Reads can be performed in privileged or problem state.

5.3.5 Program Priority Register

Privileged programs may set a wider range of program priorities in the PRI field of PPR and PPR32 than may be set by problem state programs (see Chapter 3 of Book II). Problem state programs may only set values in the range of 0b001 to 0b100 unless the Problem State Priority Boost register (see Section 5.3.6) allows the value 0b101. Privileged programs may set values in the range of 0b001 to 0b110. Hypervisor software may also set 0b111. For all priorities except 0b101, if a program attempts to set a value that is not allowed for its privilege level, the PRI field remains unchanged. If a problem state program attempts to set its priority value to 0b101 when this priority value is not allowed for problem state programs, the priority is set to 0b100.

The values and their corresponding meanings are as follows.

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>11:13</td>
<td>Program Priority (PRI)</td>
</tr>
</tbody>
</table>

- 001 very low
- 010 low
- 011 medium low
- 100 medium
- 101 medium high
- 110 high
- 111 very high

5.3.6 Problem State Priority Boost Register

The Problem State Priority Boost (PSPB) register is a 32-bit register that controls whether problem state pro-
grams have access to program priority medium high. (See Section 3.1 of Book II.)

Figure 13. Problem State Priority Boost Register
A problem state program is able to set the program priority to medium high only when the PSPB of the thread contains a non-zero value.

The maximum value to which the PSPB can be set must be a power of 2 minus 1. Bits that are not required to represent this maximum value must return 0s when read regardless of what was written to them.

When the PSPB is set to a value less than its maximum value but greater than 0, its contents decrease monotonically at the same rate as the SPURR until its contents minus the amount it is to be decreased are 0 or less when a problem state program is executing on the thread at a priority of medium high. When the contents of the PSPB minus the amount it is to be decreased are 0 or less, its contents are replaced by 0.

When the PSPB is set to its maximum value or 0, its contents do not change until it is set to a different value.

Whenever the priority of a thread is medium high and either of the following conditions exist, hardware changes the priority to medium:
- the PSPB counts down to 0, or
- PSPB=0 and the privilege state of the thread is changed to problem state (MSR_{PR}=1).

5.3.7 Relative Priority Register
The Relative Priority Register (RPR) is a 64-bit register that allows the hypervisor to control the relative priorities corresponding to each valid value of PPR_{PRI}.

<table>
<thead>
<tr>
<th>/</th>
<th>RP₁</th>
<th>RP₂</th>
<th>RP₃</th>
<th>RP₄</th>
<th>RP₅</th>
<th>RP₆</th>
<th>RP₇</th>
</tr>
</thead>
<tbody>
<tr>

<td>8</td>
<td>16</td>
<td>24</td>
<td>32</td>
<td>40</td>
<td>48</td>
<td>56</td>
</tr>
</tbody>
</table>

Figure 14. Relative Priority Register
Each RPₙ field is defined as follows.

<table>
<thead>
<tr>
<th>Bits</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:1</td>
<td>Reserved</td>
</tr>
</tbody>
</table>
| 2:7  | Relative priority of priority level n: Specifies the relative priority that corresponds to the priority corresponding to \( \text{PPR}_{PRI}=n \), where a value of 0 indicates the lowest relative priority and a value of 0b11111111 indicates the highest relative priority.

Program Note
The hypervisor must ensure that the values of the RPₙ fields increase monotonically for each n and are of different enough magnitudes to ensure that each priority level provides a meaningful difference in priority.

5.3.8 Software-use SPRs
Software-use SPRs are 64-bit registers provided for use by software.

<table>
<thead>
<tr>
<th></th>
<th>SPRG0</th>
<th>SPRG1</th>
<th>SPRG2</th>
<th>SPRG3</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>63</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Figure 15. Software-use SPRs
SPRG0, SPRG1, and SPRG2 are privileged registers. SPRG3 is a privileged register except that the contents may be copied to a GPR in Problem state when accessed using the \( \text{mfspr} \) instruction.

Program Note
Neither the contents of the SPRGs, nor accessing them using \( \text{mfspr} \) or \( \text{mfspr} \), has a side effect on the operation of the thread. One or more of the registers is likely to be needed by interrupt handlers that run in privileged non-hypervisor state (e.g., as scratch registers and/or pointers to per thread save areas).

Operating systems must ensure that no sensitive data are left in SPRG3 when a problem state program is dispatched, and operating systems for secure systems must ensure that SPRG3 cannot be used to implement a “covert channel” between problem state programs. These requirements can be satisfied by clearing SPRG3 before passing control to a program that will run in problem state.

HSPRG0 and HSPRG1 are 64-bit registers provided for use by hypervisor programs.

<table>
<thead>
<tr>

<td>63</td>
</tr>
</tbody>
</table>

Figure 17. SPRs for use by ultravisor programs

Programming Note

Neither the contents of the HSPRGs, nor accessing them using `mtspr` or `mfspr`, has a side effect on the operation of the thread. One or both of the registers is likely to be needed by interrupt handlers that run in hypervisor non-ultravisor state (e.g., as scratch registers and/or pointers to per thread save areas).

Programming Note

Neither the contents of the USPRGs, nor accessing them using `mtspr` or `mfspr`, has a side effect on the operation of the thread. One or both of the registers is likely to be needed by interrupt handlers that run in ultravisor state (e.g., as scratch registers and/or pointers to per thread save areas).
5.4 Fixed-Point Facility Instructions

5.4.1 Fixed-Point Load and Store Caching Inhibited Instructions

The storage accesses caused by the instructions described in this section are performed as though the specified storage location is Caching Inhibited and Guarded. The instructions can be executed only in hypervisor state. Software must ensure that the specified storage location is not in the caches. If the specified storage location is in a cache, the results are undefined.

The Fixed-Point Load and Store Caching Inhibited instructions must be executed only when MSR\textsubscript{DR}=0. The storage location specified by the instructions must not be in storage specified by the Hypervisor Real Mode Storage Control facility to be treated as non-Guarded. If either of these conditions is violated, the result is a Data Storage interrupt.

---

**Programming Note**

The instructions described in this section can be used to permit a control register on an I/O device to be accessed without permitting the corresponding storage location to be copied into the caches.

The Fixed-Point Load and Store Caching Inhibited instructions are fixed-point Storage Access instructions; see Section 3.3.1 of Book I.
**Load Byte and Zero Caching Inhibited Indexed X-form**

\[
\text{lbzcix} \quad \text{RT,RA,RB}
\]

The storage access caused by this instruction is performed as though the specified storage location is Caching Inhibited and Guarded.

This instruction is hypervisor privileged.

Special Registers Altered:
None
5.4.2 OR Instruction

or Rx,Rx,Rx can be used to set PPRPRI (see Section 5.3.5) as shown in Figure 18. For all priorities except medium high, PPRPRI remains unchanged if the privilege state of the thread executing the instruction is lower than the privilege indicated in the figure. For priority medium high, PPRPRI is set to medium if the thread executing the instruction is in problem state and medium high priority is not allowed for problem state programs. (The encodings available to problem state programs, as well as encodings for additional shared resource hints not shown here, are described in Chapter 3 of Book II.)

<table>
<thead>
<tr>

</tbody>
</table>

¹This value is privileged unless the Problem State Priority Boost register allows the priority value 0b101 (See Section 5.3.6.)

Figure 18. Priority levels for or Rx,Rx,Rx

5.4.3 OR Immediate Instruction

ori R31,R31,0 is a no-op instruction that is also execution serializing: that is, executing an ori R31,R31,0 instruction ensures that all instructions preceding the ori R31,R31,0 instruction have completed before the ori R31,R31,0 instruction completes, and that no subsequent instructions are initiated, even out-of-order, until after the ori R31,R31,0 instruction completes.

The ori R31,R31,0 instruction may complete before storage accesses associated with instructions preceding the ori R31,R31,0 instruction have been performed.

Extended Mnemonics:

Additional extended mnemonic for the execution serializing form of Or Immediate:

<table>
<thead>
<tr>
<th>Extended</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td>exser</td>
<td>ori 31,31,0</td>
</tr>
</tbody>
</table>

Warning: Other forms of ori Rx,Rx,0 that are not described in this section may also have micro-architectural effects on program execution. Use of these forms should be avoided except when software needs the associated micro-architectural effects. If a no-op is needed, the preferred no-op (ori 0,0,0) should be used.

5.4.4 Move To/From System Register Instructions

The Move To Special Purpose Register and Move From Special Purpose Register instructions are described in Book I, but only at the level available to an application programmer. For example, no mention is made there of registers that can be accessed only in privileged state. The descriptions of these instructions given below extend the descriptions given in Book I, but do not list Special Purpose Registers that are implementation-dependent. In the descriptions of these instructions given in below, the “defined” SPR numbers are the SPR numbers shown in the Figure 19 for the instruction and the implementation-specific SPR numbers that are implemented, and similarly for “defined” registers. All other SPR numbers are undefined for the instruction. (Implementation-specific SPR numbers that are not implemented are considered to be undefined.) When an SPR is defined for mtspr and undefined for mfspr, or vice versa, a hyphen appears in the column for the instruction for which the SPR number is undefined.

SPR numbers that are not shown in Figure 19 and are in the ranges shown below are reserved for implementation-specific uses.

<table>
<thead>
<tr>
<th>SPR Numbers for Specific Uses</th>
</tr>
</thead>
<tbody>
<tr>
<td>848 - 863</td>
</tr>
<tr>
<td>880 - 895</td>
</tr>
<tr>
<td>976 - 991</td>
</tr>
<tr>
<td>1008 - 1023</td>
</tr>
</tbody>
</table>

Implementation-specific registers must be privileged. SPR numbers for implementation-specific SPRs should be registered in advance with the Power ISA architects.

</tbody>
</table>

1. This register is not defined for this instruction.
2. Note that the order of the two 5-bit halves of the SPR number is reversed.
3. This register is a hypervisor resource, and can be accessed by this instruction only in hypervisor state (see Chapter 2).
4. This register cannot be directly written. Instead, bits in the register corresponding to 0 bits in (RS) can be cleared using **mtspr** SPR,RS.
5. The value specified in register RS may be masked by the contents of the [U]AMOR before being placed into the AMR; see the **mtspr** instruction description.
6. MMCR₀ᵖMCC and MMCR₀ᵖMCCEXT controls the availability of this SPR, and its contents depend on the privilege state in which it is accessed. See Section 10.4.4 for details.
7. The value specified in Register RS may be masked by the contents of the AMOR before being placed into the IAMR; see the **mtspr** instruction description.
8. The `mftb` instruction is Phased-Out. Assemblers targeting Version 2.03 or later of the architecture should generate an **mfspr** instruction for the `mftb` and `mftbu` extended mnemonics; see the corresponding Assembler Note in the **mftb** instruction description (see Section 5.1 of Book II).
9. No extended mnemonic is provided because previous versions of the architecture defined the obvious extended mnemonic as resolving to the non-privileged SPR number, and because there is no software benefit in using the privileged SPR number, rather than the non-privileged SPR number, for this function.
10. `mfspr` specifying this register is ultravisor privileged when SMFCTRLD=1; otherwise it is hypervisor privileged.

*This figure also defines extended mnemonics for the **mtspr** and **mfspr** instructions, including the Special Purpose Registers (SPRs) defined in Book I and for the **Move From Time Base** instruction defined in Book II.

The **mtspr** and **mfspr** instructions specify an SPR as a numeric operand; extended mnemonics are provided that represent the SPR in the mnemonic rather than requiring it to be coded as an operand. Similar extended mnemonics are provided for the **Move From Time Base** instruction, which specifies the portion of the Time Base as a numeric operand.

**Note:** The `mftb` serves as both a basic and an extended mnemonic. The Assembler will recognize an `mftb` mnemonic with two operands as the basic form, and an `mftb` mnemonic with one operand as the extended form. In the extended form the TBR operand is omitted and assumed to be 268 (the value that corresponds to TB).

    else
      SPR(n) ← (RS) 32:63
```

The SPR field denotes a Special Purpose Register, encoded as shown in Figure 19. If the SPR field contains the value 158, the instruction is treated as a privileged no-op. If the SPR field contains a value from 808 through 811, the instruction specifies a reserved SPR, and is treated as a no-op; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I. Otherwise, the contents of register RS are placed into the designated Special Purpose Register, except as described in the next five paragraphs. For Special Purpose Registers that are 32 bits long, the low-order 32 bits of RS are placed into the SPR.

When the designated SPR is the Authority Mask Register (AMR), (using SPR 13 or SPR 29), or the designated SPR is the Instruction Authority Mask Register (IAMR), and MSRHV PR=0b00, the contents of bit positions of register RS corresponding to 1 bits in the Authority Mask Override Register (AMOR) are placed into the corresponding bits of the AMR or IAMR, respectively; the other AMR or IAMR bits are not modified.

When the designated SPR is the AMR, using SPR 13, and MSRPR=1, the contents of bit positions of register RS corresponding to 1 bits in the User Authority Mask Override Register (UAMOR) are placed into the corresponding bits of the AMR; the other AMR bits are not modified.

When the designated SPR is the Hypervisor Maintenance Exception Register (HMER), the contents of register RS are ANDed with the contents of the HMER and the result is placed into the HMER.

For this instruction, SPRs TBL and TBU are treated as separate 32-bit registers; setting one leaves the other unaltered.

spr0=1 if and only if writing the register is privileged. Execution of this instruction specifying an SPR number with spr0=1 when the privilege state of the thread does not permit the access causes one of the following.

- **MSRPR=1**: Privileged Instruction type Program interrupt
- **MSHV PR=0b00 or MSR S HV PR=0b010 and the SPR is always an ultravisor resource (independent of the contents of SMFCTRL)**: Privileged Instruction type Program interrupt
- **MSRHV PR=0b00 and the SPR is a hypervisor resource (see Figure 19) or is PTCR, DAWRn, DAWRXn, or CIABR when they are ultravisor privileged for the operation**: Hypervisor Emulation Assistance interrupt

Execution of this instruction specifying an SPR number that is undefined for the implementation causes one of the following.

- if spr0=0:
  - if MSRPR=1: Hypervisor Emulation Assistance interrupt
  - if MSRPR=0: Privileged Instruction type Program interrupt
- if spr0=1:
  - if MSRPR=1: Privileged Instruction type Program interrupt
  - if MSRPR=0: no operation (i.e., the instruction is treated as a no-op) when LPCREVIRT=0 and Hypervisor Emulation Assistance interrupt when LPCREVIRT=1 for all other SPRs

Chapter 5. Fixed-Point Facility  1171
Special Registers Altered:
See Figure 19

---

**Programming Note**

For a discussion of software synchronization requirements when altering certain Special Purpose Registers, see Chapter 12, "Synchronization Requirements for Context Alterations" on page 1333.

---

**Programming Note**

Requiring that an attempt to execute an `mtspr` or `mfspr` instruction with SPR=0 or an attempt to execute an `mfspr` instruction with SPR=4, 5, or 6 cause a Hypervisor Emulation Assistance interrupt permits efficient emulation of `mt/lspr` specifying the corresponding SPRs as defined in the POWER Architecture.

Requiring that an attempt to execute an `mtspr` instruction with SPR=4, 5, or 6 cause a Hypervisor Emulation Assistance interrupt, even in privileged state, makes the behavior be the same for both instructions for all four SPR numbers, thereby simplifying the architecture. (SPRs 4, 5, and 6 were not defined for `mtspr` in the POWER Architecture. The corresponding SPRs were privileged for writing, and `mtspr` to those SPRs used the corresponding privileged SPR number.)
Move From Special Purpose Register

The SPR field denotes a Special Purpose Register, encoded as shown in Figure 19. If the SPR field contains a value from 808 through 811, the instruction specifies a reserved SPR, and is treated as a no-op; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I. Otherwise, the contents of the designated Special Purpose Register are placed into register RT. For Special Purpose Registers that are 32 bits long, the low-order 32 bits of RT receive the contents of the Special Purpose Register and the high-order 32 bits of RT are set to zero.

spr0=1 if and only if reading the register is privileged. Execution of this instruction specifying an SPR number with spr0=1 when the privilege state of the thread does not permit the access causes one of the following.

- if MSRPR=0: Hypervisor Emulation Assistance interrupt for SPRs 0, 4, 5, and 6, and no operation (i.e., the instruction is treated as a no-op) when LPCR_EV=0 and Hypervisor Emulation Assistance interrupt when LPCR_EV=1 for all other SPRs
- if spr0=1:
  - if MSRPR=1: Privileged Instruction type Program interrupt
  - if MSRPR=0: no operation (i.e., the instruction is treated as a no-op) when LPCR_EV=0 and Hypervisor Emulation Assistance interrupt when LPCR_EV=1

Special Registers Altered:
None

Note
See the Notes that appear with mt spr.
Move To Machine State Register X-form

Let $L = 0$ then
- $MSR_{48} \leftarrow (RS)_{48} \mid (RS)_{49}$
- $MSR_{58} \leftarrow (RS)_{58} \mid (RS)_{49}$
  - $\neg(MSR_{41} \& MSR_3 \& (\neg (RS)_{49}))$
- $MSR_{59} \leftarrow (RS)_{59} \mid (RS)_{49}$
  - $\neg(MSR_{41} \& MSR_3 \& (\neg (RS)_{49}))$

Let $L = 1$ then
- $MSR_{48, 62} \leftarrow (RS)_{48, 62}$

The MSR is set based on the contents of register RS and of the L field.

$L=0$: The result of ORing bits 48 and 49 of register RS is placed into MSR$_{48}$. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of register RS is complemented and then ANDed with the result of ORing bits 58 and 49 of register RS and placed into MSR$_{58}$. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of register RS is complemented and then ANDed with the result of ORing bits 59 and 49 of register RS and placed into MSR$_{59}$. Bits 32:40, 42:47, 49:50, 52:57, and 60:62 of register RS are placed into the corresponding bits of the MSR.

$L=1$: Bits 48 and 62 of register RS are placed into the corresponding bits of the MSR. The remaining bits of the MSR are unchanged.

This instruction is privileged.

If $L=0$ this instruction is context synchronizing. If $L=1$ this instruction is execution synchronizing; in addition, the alteration of the EE and RI bits take effect as soon as the instruction completes.

Special Registers Altered:
- MSR

Except in the mtmsr instruction description in this section, references to “mtmsr” in this document imply either $L$ value unless otherwise stated or obvious from context (e.g., a reference to an mtmsr instruction that modifies an MSR bit other than the EE or RI bit implies $L=0$).
Move To Machine State Register
Doubleword  X-form

if L = 0 then

\[
\begin{align*}
\text{MSR}_{48} & \leftarrow (\text{RS})_{48} \lor (\text{RS})_{49} \\
\text{MSR}_{58} & \leftarrow (\text{RS})_{58} \lor (\text{RS})_{49} \\
& \land \neg (\text{MSR}_{41} \land \text{MSR}_3 \land \neg (\text{RS})_{49}) \\
\text{MSR}_{59} & \leftarrow (\text{RS})_{59} \lor (\text{RS})_{49} \\
& \land \neg (\text{MSR}_{41} \land \text{MSR}_3 \land \neg (\text{RS})_{49}) \\
\text{MSR}_{0:2} & \leftarrow 4:40 \lor 42:47 \lor 49:50 \lor 52:57 \lor 60:62 \\
\text{LSB} & \leftarrow (\text{RS})_{0:2} \lor 4:40 \lor 42:47 \lor 49:50 \lor 52:57 \lor 60:62
\end{align*}
\]

else

\[
\text{MSR}_{48} \leftarrow (\text{RS})_{48} \lor 62
\]

The MSR is set based on the contents of register RS and of the L field.

L=0:

The result of ORing bits 48 and 49 of register RS is placed into MSR\(_{48}\). The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of register RS is complemented and then ANDed with the result of ORing bits 58 and 49 of register RS and placed into MSR\(_{58}\). The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of register RS is complemented and then ANDed with the result of ORing bits 59 and 49 of register RS and placed into MSR\(_{59}\). Bits 0:2, 4:40, 42:47, 49:50, 52:57, and 60:62 of register RS are placed into the corresponding bits of the MSR.

L=1:

Bits 48 and 62 of register RS are placed into the corresponding bits of the MSR. The remaining bits of the MSR are unchanged.

This instruction is privileged.

If L=0 this instruction is context synchronizing. If L=1 this instruction is execution synchronizing; in addition, the alterations of the EE and RI bits take effect as soon as the instruction completes.

Special Registers Altered:

MSR

Except in the mtmsrd instruction description in this section, references to “mtmsrd” in this document imply either L value unless otherwise stated or obvious from context (e.g., a reference to an mtmsrd instruction that modifies an MSR bit other than the EE or RI bit implies L=0).

---

Programming Note

If this instruction sets MSR\(_{PR}\) to 1, it also sets MSR\(_{EE}\), MSR\(_{IR}\), and MSR\(_{DR}\) to 1. If this instruction results in MSRS\(_{HV}\) being equal to 0b110, it also sets MSR\(_{IR}\) and MSR\(_{DR}\) to 0.

This instruction does not alter MSRS\(_{HV}\), MSRS\(_{S}\), MSRS\(_{ME}\), or MSRS\(_{LE}\).

If the only MSR bits to be altered are MSRS\(_{EE,RI}\), to obtain the best performance L=1 should be used.

---

Programming Note

If MSRS\(_{EE}\)=0 and an External, Decrementer, or Performance Monitor exception is pending, executing an mtmsrd instruction that sets MSRS\(_{EE}\) to 1 will cause the interrupt to occur before the next instruction is executed, if no higher priority exception exists (see Section 7.9, “Interrupt Priorities” on page 1290). Similarly, if a Hypervisor Decrementer interrupt is pending, execution of the instruction by the hypervisor causes a Hypervisor Decrementer interrupt to occur if HDICE=1.

For a discussion of software synchronization requirements when altering certain MSR bits, see Chapter 12.

---

Programming Note

mtmsrd serves as both a basic and an extended mnemonic. The Assembler will recognize an mtmsrd mnemonic with two operands as the basic form, and an mtmsrd mnemonic with one operand as the extended form. In the extended form the L operand is omitted and assumed to be 0.
Move From Machine State Register

\[ \text{mfmsr} \quad \text{RT} \]

\[
\begin{array}{cccccc}
31 & \text{RT} & /// & /// & 83 & \backslash
\end{array}
\]

RT ← MSR

The contents of the MSR are placed into register RT.

This instruction is privileged.

Special Registers Altered:

None
Chapter 6. Storage Control

6.1 Overview
A program references storage using the effective address computed by the hardware when it executes a Load, Store, Branch, or Cache Management instruction, or when it fetches the next sequential instruction. The effective address is translated to a real address according to procedures described in Section 6.7.3, in Section 6.7.7 and in the following sections. The real address is what is presented to the storage subsystem.

For a complete discussion of storage addressing and effective address calculation, see Section 1.10 of Book I.

6.2 Storage Exceptions
A storage exception results when the sequential execution model requires that a storage access be performed but the access is not permitted (e.g., is not permitted by the storage protection mechanism), the access cannot be performed because the effective address cannot be translated to a real address, or the access matches some tracking mechanism criteria (e.g., Data Address Watchpoint).

In certain cases a storage exception may result in the “restart” of (re-execution of at least part of) a Load or Store instruction. See Section 6.7 in this Book.

6.3 Instruction Fetch
Instructions are fetched under control of MSRIR.

MSRIR=0
The effective address of the instruction is interpreted as described in Section 6.7.3.

MSRIR=1
The effective address of the instruction is translated by the Address Translation mechanism described beginning in Section 6.7.7.

6.3.1 Implicit Branch
Explicitly altering certain MSR bits (using mtmsr[if]), or explicitly altering SLB entries, Page Table Entries, or certain System Registers (including the HRMOR, URMOR, and possibly other implementation-dependent registers), may have the side effect of changing the addresses, effective or real, from which the current instruction stream is being fetched. This side effect is called an implicit branch. For example, an mtmsrd instruction that changes the value of MSR_SF may change the effective addresses from which the current instruction stream is being fetched. The MSR bits and System Registers (excluding implementation-dependent registers) for which alteration can cause an implicit branch are indicated as such in Chapter 12. “Synchronization Requirements for Context Alterations” on page 1333. Implicit branches are not supported by the Power ISA. If an implicit branch occurs, the results are boundedly undefined.

6.3.2 Address Wrapping Combined with Changing MSR Bit SF
If the current instruction is at effective address $2^{32} - 4$ and is an mtmsrd instruction that changes the contents of MSR_SF, the effective address of the next sequential instruction is undefined.

Programming Note

If the thread is in 32-bit mode, the current instruction is a word instruction at effective address $2^{32} - 4$ or a prefixed instruction at effective address $2^{32} - 8$, and an interrupt occurs that is defined to set SRR0 or HSRR0 (or LR, for the System Call Vectored interrupt) to the effective address of the next sequential instruction, the contents of SRR0 or HSRR0 (or LR), as appropriate to the interrupt, are undefined.
6.4 Data Access

Data accesses are controlled by MSR\textsubscript{DR}.

\textbf{MSR\textsubscript{DR}}=0

The effective address of the data is interpreted as described in Section 6.7.3.

\textbf{MSR\textsubscript{DR}}=1

The effective address of the data is translated by the Address Translation mechanism described in Section 6.7.7.

6.5 Performing Operations Out-of-Order

An operation is said to be performed “in-order” if, at the time that it is performed, it is known to be required by the sequential execution model. An operation is said to be performed “out-of-order” if, at the time that it is performed, it is not known to be required by the sequential execution model.

Operations are performed out-of-order on the expectation that the results will be needed by an instruction that will be required by the sequential execution model. Whether the results are really needed is contingent on everything that might divert the control flow away from the instruction, such as \textit{Branch, Trap, System Call}, and \textit{Return From Interrupt} instructions, and interrupts, and on everything that might change the context in which the instruction is executed.

Typically, operations are performed out-of-order when resources are available that would otherwise be idle, so the operation incurs little or no cost. If subsequent events such as branches or interrupts indicate that the operation would not have been performed in the sequential execution model, any results of the operation are abandoned (except as described below).

In the remainder of this section, including its subsections, “Load instruction” includes the \textit{Cache Management} and other instructions that are stated in the instruction descriptions to be “treated as a Load”, and similarly for “Store instruction”.

A data access that is performed out-of-order may correspond to an arbitrary \textit{Load} or \textit{Store} instruction (e.g., a \textit{Load} or \textit{Store} instruction that is not in the instruction stream being executed). Similarly, an instruction fetch that is performed out-of-order may be for an arbitrary instruction (e.g., the aligned word at an arbitrary location in instruction storage).

Most operations can be performed out-of-order, as long as the machine appears to follow the sequential execution model. Certain out-of-order operations are restricted, as follows.

\textbullet\ Stores are not performed out-of-order (even if the Store instructions that caused them were executed out-of-order).

\textbullet\ Accessing Guarded Storage

The restrictions for this case are given in Section 6.8.1.1.

\textbullet\ Executing instructions subsequent to an \texttt{ori R31,R31,0} instruction

The restrictions for this case are given in Section 5.4.3.

The only permitted side effects of performing an operation out-of-order are the following.

\textbullet\ A Machine Check or Checkstop that could be caused by in-order execution may occur out-of-order.

\textbullet\ Reference and Change bits may be set as described in Section 6.7.12.

\textbullet\ Non-Guarded storage locations that could be fetched into a cache by in-order fetching or execution of an arbitrary instruction may be fetched out-of-order into that cache.

6.6 Invalid Real Address

A storage access (including an access that is performed out-of-order; see Section 6.5) may cause a Machine Check if the accessed storage location contains an uncorrectable error or does not exist.

In the case that the accessed storage location does not exist, the Checkstop state may be entered. See Section 7.5.2 on page 1264.

\begin{center}
\textbf{Programming Note}
\end{center}

In configurations supporting multiple partitions, hypervisor software must ensure that a storage access by a program in one partition will not cause a Checkstop or other system-wide event that could affect the integrity of other partitions (see Chapter 2). For example, such an event could occur if a real address placed in a Page Table Entry does not exist.
6.7 Storage Addressing

Storage Control Overview

- Host real address space size is 2^m bytes, m≤60; see Note 1.
- Guest real address space size is 2^m bytes, m≤60; see Notes 1 and 2.
- Real page size is 2^{12} bytes (4 KB).
- Effective address space size is 2^{64} bytes.

For HPT translation, an effective address is translated to a virtual address via a segment descriptor that was either bolted into the Segment Lookaside Buffer (SLB) by software or found and installed into the SLB via a hardware walk of the Segment Table. After that, the virtual address is translated to a host real address via a hardware walk of the Page Table.
- Virtual address space size is 2^{n} bytes, 65≤n≤78; see Note 3.
- Segment size is 2^{s} bytes, s=28 or 40.
- 2^{n-40} ≤ number of virtual segments ≤ 2^{n-28}; see Note 3.
- Virtual page size is 2^{p} bytes, where 12≤p, and 2^{p} is no larger than either the size of the biggest segment or the real address space; a size of 4 KB, 64 KB, and an implementation-dependent number of other sizes are supported; see Note 3. The Page Table specifies the virtual page size. The SLB specifies the base virtual page size, which is the smallest virtual page size that the segment can contain. The base virtual page size is 2^{b} bytes.
- Segments contain pages of a single size, a mixture of 4 KB and 64 KB pages, or a mixture of page sizes that include implementation-dependent page sizes.

For Radix Tree translation, an effective address is translated to a (guest or host) real address via a hardware walk of the Page Table.
- Virtual page size is 2^{p} bytes, where 12≤p, and 2^{p} is no larger than the size of the real address space; a size of 4 KB, 64 KB, 2MB, and an implementation-dependent number of other sizes are supported; see Note 4. The Page Table specifies the virtual page size. The SLB specifies the base virtual page size, which is the smallest virtual page size that the segment can contain. The base virtual page size is 2^{b} bytes.

Notes:

1. The value of m is implementation-dependent (subject to the maximum given above). When used to address storage or to represent a guest real address, the high-order 60-m bits of the "60-bit" real address must be zeros.

2. The hypervisor may assign a guest real address space size for each partition that uses Radix Tree translation. Accesses to guest real storage outside this range but still mappable by the second level Radix Tree will cause an HiSI or HDSI. Accesses to storage outside the mappable range will have boundedly undefined results.

3. The value of n is implementation-dependent (subject to the range given above). In references to 78-bit virtual addresses elsewhere in this Book, the high-order 78-n bits of the “78-bit” virtual address are assumed to be zeros.

4. The supported values of p for the larger virtual page sizes are implementation-dependent (subject to the limitations given above).

---

Programming Note

Note that without some of the reserved bits in the Radix PTE, the RPN field cannot address the full 60-bit real address space. Similarly without some of the reserved bits in the HPT PTE, the ARPN field cannot address the full 60-bit real address space. Note that without some of the reserved bits in the HPT PTE, the AVA field cannot resolve the full 78-bit virtual address.

6.7.1 32-Bit Mode

The computation of the 64-bit effective address is independent of whether the thread is in 32-bit mode or 64-bit mode. In 32-bit mode (MSRF=0), the high-order 32 bits of the 64-bit effective address are treated as zeros for the purpose of addressing storage. This applies to both data accesses and instruction fetches. It applies independent of whether address translation is enabled or disabled. This truncation of the effective address is the only respect in which storage accesses in 32-bit mode differ from those in 64-bit mode.

---

Programming Note

Treating the high-order 32 bits of the effective address as zeros effectively truncates the 64-bit effective address to a 32-bit effective address such as would have been generated on a 32-bit implementation of the Power ISA. Thus, for example, the ESID in 32-bit mode is the high-order four bits of this truncated effective address; the ESID thus lies in the range 0-15. When address translation is enabled, these four bits would select a Segment Register on a 32-bit implementation of the Power ISA. The SLB entries that translate these 16 ESIDs can be used to emulate these Segment Registers.
6.7.2 Virtualized Partition Memory (VPM) Mode

VPM mode enables the hypervisor to reassign all or part of a partition’s memory transparently so that the reassignment is not visible to the partition. When this is done, the partition’s memory is said to be “virtualized.” This mode is only available within Paravirtualized HPT translation mode. Radix Tree translation mode provides equivalent function by providing two levels of translation with separate Page Tables for the operating system and the hypervisor. (See Section 6.7.7 for a more complete overview of the translation modes.) The VPM field in the LPCR enables VPM mode when address translation is enabled. VPM is always enabled when address translation is disabled.

If the thread is not in hypervisor state, and either address translation is enabled and VPM=1, or address translation is disabled, conditions that would have caused a Data Storage or an Instruction Storage interrupt if the affected memory were not virtualized instead cause a Hypervisor Data Storage or a Hypervisor Instruction Storage interrupt respectively. Because the Hypervisor Data Storage and Hypervisor Instruction Storage interrupts always put the thread in hypervisor state, they permit the hypervisor to handle the condition if appropriate (e.g., to restore the contents of a page that was reassigned), and to reflect it to the operating system’s Data Storage or Instruction Storage interrupt handler otherwise.

When address translation is enabled, VPM mode has no effect on address translation. When address translation is disabled, addressing is controlled as specified in Section 6.7.3.

6.7.3 Ultravisor Real, Hypervisor Real, and Virtual Real Addressing Modes

If a storage access is an instruction fetch performed when instruction address translation is disabled, or if the access is a data access performed when data address translation is disabled, it is said to be performed in “ultravisor real addressing mode” if the thread is in ultravisor state, in “hypervisor real addressing mode” if the thread is in hypervisor non-ultravisor state, and in “virtual real addressing mode” if the thread is in privileged non-hypervisor state. Storage accesses in ultravisor real, hypervisor real, and virtual real addressing modes are performed in a manner that depends on the contents of MSR<sub>HV</sub>, PATE<sub>HR</sub>, PATE<sub>PS</sub>, URMOR (see Chapter 3), HRMOR (see Chapter 2), bit 0 of the effective address (EA<sub>0</sub>), and the state of the Real Mode Storage Control Facility as described below. Bits 1:3 of the effective address are ignored.

MSRs<sub>HV</sub>=0b11
- If EA<sub>0</sub>=0, the Ultravisor Offset Real Mode Address mechanism, described in Section 6.7.3.1, controls the access.
- If EA<sub>0</sub>=1, bits 4:63 of the effective address are used as the real address for the access.

MSRs<sub>HV</sub>=0b01
- If EA<sub>0</sub>=0, the Hypervisor Offset Real Mode Address mechanism, described in Section 6.7.3.1, controls the access.
- If EA<sub>0</sub>=1, bits 4:63 of the effective address are used as the real address for the access.

MSR<sub>HR</sub>=0
- If PATE<sub>HR</sub>=0, the Virtual Real Mode Addressing mechanism, described in Section 6.7.3.3, controls the access.
- If PATE<sub>HR</sub>=1, partition-scoped translation is performed on the effective address. (See Section 6.7.11.3, “Obtaining Host Real Address, Radix on Radix”.)

6.7.3.1 Ultravisor/Hypervisor Offset Real Mode Address

If MSR<sub>HV</sub> = 1 and EA<sub>0</sub> = 0, the access is controlled by the contents of the Ultravisor Real Mode Offset Register or the Hypervisor Real Mode Offset Register, depending on the value of MSR<sub>S</sub>, as follows.

Ultravisor Real Mode Offset Register (URMOR)

When MSR<sub>S</sub>=1, bits 4:63 of the effective address for the access are ORed with the 60-bit offset represented by the contents of the URMOR, and the 60-bit result is used as the real address for the access.

Hypervisor Real Mode Offset Register (HRMOR)

When MSR<sub>S</sub>=0, bits 4:63 of the effective address for the access are ORed with the 60-bit offset represented by the contents of the HRMOR, and the 60-bit result is used as the real address for the access.

For each of the two registers, the supported offset values are all values of the form \(i \times 2^j\), where \(0 \leq i < 2^j\), and \(j\) and \(r\) are implementation-dependent values having the properties that \(12 \leq r \leq 26\) (i.e., the minimum offset granularity is 4 KB and the maximum offset granularity is 64 MB) and \(j + r = m\), where the real address size supported by the implementation is \(m\) bits.
Chapter 6. Storage Control

6.7.3.2 Storage Control Attributes for Accesses in Ultravisor and Hypervisor Real Addressing Modes

Storage accesses in ultravisor and hypervisor real addressing modes are performed as though all of storage had the following storage control attributes, except as modified by the Hypervisor Real Mode Storage Control facility (see Section 6.7.3.2.1). (The storage control attributes are defined in Book II.)

- not Write Through Required
- not Caching Inhibited, for instruction fetches
- not Caching Inhibited, for data accesses except those caused by the Load/Store Caching Inhibited instructions; Caching Inhibited, for data accesses caused by the Load/Store Caching Inhibited instructions
- Memory Coherence Required, for data accesses
- Guarded

Additionally, storage accesses in ultravisor and hypervisor real addressing modes are performed as though all storage was not No-execute.

Programming Note

Because storage accesses in ultravisor and hypervisor real addressing modes do not use the SLB or the Page Table, accesses in these modes bypass all checking and recording of information contained therein (e.g., storage protection checks that use information contained therein are not performed, and reference and change information is not recorded).

6.7.3.2.1 Hypervisor Real Mode Storage Control

The Hypervisor Real Mode Storage Control facility provides a means of specifying portions of real storage that are treated as neither Caching Inhibited nor Guarded in ultravisor and hypervisor real addressing modes (MSR\textsubscript{hyp PR}=0b10, and MSR\textsubscript{RR}=0 or MSR\textsubscript{DR}=0, as appropriate for the type of access). The remaining portions are treated as Caching Inhibited and Guarded in ultravisor and hypervisor real addressing modes.

The means is a hypervisor resource (see Chapter 2), and may also be system-specific.

The facility divides real storage into history blocks, in implementation-specific sizes. The history for instruction fetches is tracked separately from that for data accesses. If there is no instruction fetch history for a block and it is the target of an instruction fetch, the access is performed as though the block is Guarded, but the block is treated as not Guarded for subsequent instruction fetches on a best effort basis, limited by the amount of history that the facility can maintain. If there is no data access history for a block and it is accessed using a Load/Store Caching Inhibited instruction, the access is performed as though the block is Guarded, and the block is treated as Guarded for subsequent accesses on a best effort basis, limited by the amount of history that the facility can maintain. If there is no data access history for a block and it is accessed using any other Load or Store instruction, the access is performed as though the block is Guarded, but the block is treated as not Guarded for subsequent accesses on a best effort basis, limited by the amount of history that the facility can maintain. If the history causes a block to be treated as Guarded, the block is also treated as Caching Inhibited; if the history causes a block to be treated as not Guarded, the block is also treated as not Caching Inhibited.

If the storage location specified by a Load/Store Caching Inhibited instruction is in storage that is specified by the Hypervisor Real Mode Storage Control facility to be treated as not Guarded, a Data Storage interrupt occurs. ("specified by the Hypervisor Real Mode Storage Control facility" means "specified in a history block"). The history can be erased using an slbia instruction; see Section 6.9.3.2.
The facility does not apply to implicit accesses to the Page Table performed during address translation or in recording reference and change information. These accesses are performed as described in Section 6.7.3.4.

6.7.3.3 Virtual Real Mode Addressing Mechanism

If MSR[47]=0, the partition is using Paravirtualized HPT translation (PATEHR=0), and MSR[48]=0 or MSR[49]=0 as appropriate for the type of access, the access is said to be made in virtual real addressing mode and is controlled by the mechanism specified below. The set of storage locations accessible by code is referred to as the Virtualized Real Mode Area (VRMA).

In virtual real addressing mode, address translation, storage protection, and reference and change recording are handled as follows.

- Address translation and storage protection are handled as if address translation were enabled, except that translation of effective addresses to virtual addresses use the SLBE values in Figure 20 instead of the entry in the SLB corresponding to the ESID. In this translation, bits 0:23 of the effective address are ignored (i.e., treated as if they were 0s), bits 24:63-m may be ignored if m < 40, and the Virtual Page Class Key Protection mechanism does not apply.

- Reference and change recording are handled as if address translation were enabled.

The C bit in Figure 20 is set to 0 because the implementation-specific lookaside information associated with the VRMA is expected to be long-lived. See the Programming Note about Class in Section 6.7.8.1.

The 1 TB VSID 0x0_01FF_FFFF should not be used by the operating system for purposes other than mapping the VRMA when address translation is enabled.
Programming Note

Software should specify PTEB = 0b01 for all Page Table Entries that map the VRMA in order to be consistent with the values in Figure 20.

6.7.4 Definitions

translation mode: Refers to either HPT translation or Radix Tree translation. The translation mode is specified by the HR field in the Partition Table Entry corresponding to the contents of the LPIDR.

process-scoped: Refers to translation performed using tables pointed to by Process Table Entries: guest Radix Tree translation, host Radix Tree translation for quadrants 0 and 3 when MSRHV=1, or Segment translation.

partition-scoped: Refers to translation performed using tables found using the first doubleword of Partition Table Entries, either host Radix Tree translation or HPT translation.

fully-qualified address: Refers to the address to be translated, when qualified by the effective LPID and effective PID.

guest real address: Refers to the input to the partition-scoped translation process when using nested Radix Tree translation.

virtual address: Refers to the output of Segment translation and input to HPT translation.

host real address: Refers to the output of the partition-scoped translation process in nested Radix Tree translation or the output of the process-scoped translation in nested Radix Tree translation for quadrants 0 and 3 when MSRHV=1. The simpler “real address” may be used interchangeably.

Page Directory: A table within the Radix Tree translation structure that contains elements (“Page Directory Entries”) that point to other tables, instead of containing just Page Table Entries. The Page Directory that is at the root of the Radix Tree is called the “Root Page Directory.”

effLPID, effPID: This is shorthand for effective LPID and effective PID. In certain circumstances, the value used for the LPID and/or the PID is specified to be zero instead of the actual register contents. “Effective” or “eff” is used to indicate the possibility of such a substitution. This value substitution happens only in Radix Tree translation, and is based on the value of EA0:1 (see Section 6.7.5.1, “Effective Address Space Structure for Radix-using Partitions”). Value substitution does not happen in HPT translation. When a guest uses Radix Tree translation, PID substitution may take place. When a host uses Radix Tree translation, both PID and LPID substitution may take place. When a host uses HPT translation, the only special significance associated with LPIDR=0 is with regard to Segment Table walk when MSRHV=1, as described later.

adjunct: An adjunct is a software entity that resides in a partition along with an operating system and its applications in order to efficiently provide services (e.g., device drivers) for the partition. The adjunct is managed by the hypervisor. It runs in problem state with MSRHVPR=0b011, thereby restricting the resources it can modify (MSRPR=1) and causing its interrupts to go to the hypervisor (MSRHV=0b01). It shares an HPT with the partition it serves. The adjunct’s storage is kept separate from the client partition’s storage using Virtual Page Class Key protection. (The adjunct’s lightness of weight derives from not requiring a full partition context switch (SLB flush, TLB flush, PID/PID change, etc.) when the client partition invokes the services of the adjunct.) Each hardware thread may have its own unique translations for an adjunct. As a result, adjunct segment descriptors cannot exist in the process’s Segment Table and must instead be bolted in the SLB manually. The adjunct construct exists only with an HR=0 hypervisor and only for LPID≠0. The adjunct has its own 64-bit EA space. Entry to an adjunct is only possible from hypervisor state. Prior to dispatching the adjunct, the hypervisor must invalidate SLB entries that map the effective address range that will be used by the adjunct. Similarly, on exit from the adjunct, the hypervisor must invalidate its SLB entries.
6.7.5 Address Ranges Having Defined Uses

The address ranges described below have uses that are defined by the architecture.

- **Fixed interrupt vectors**
  
  Except for the first 256 bytes, which are reserved for software use, the real page beginning at real address 0x0000_0000_0000_0000 is either used for interrupt vectors or reserved for future interrupt vectors.

- **Implementation-specific use**
  
  The two contiguous real pages beginning at real address 0x0000_0000_0000_1000 are reserved for implementation-specific purposes.

- **Offset Real Mode interrupt vectors**
  
  The real pages beginning at the real addresses specified by the URMOR and the HRMOR are used similarly to the page for the fixed interrupt vectors.

- **Relocated interrupt vectors**
  
  Depending on the values of MSR$_{HV}$, MSR$_{IR}$, MSR$_{DR}$ when the interrupt occurs and on the value of LPCR$_{AIL}$, LPCR$_{HAIL}$ as appropriate, the virtual page containing the byte addressed by effective address 0xC000_0000_0000_4000 may be used similarly to the page for the fixed interrupt vectors. (See Section 2.2.)

- **System Call Vectored interrupt vectors**
  
  Depending on the values of MSR$_{HV}$, MSR$_{IR}$, MSR$_{DR}$ when the interrupt occurs and on the value of LPCR$_{AIL}$, LPCR$_{HAIL}$ as appropriate, the virtual page containing the byte addressed by effective address 0xC000_0000_0000_3000 contains the interrupt vectors that are invoked by the System Call Vectored instruction. (See Section 2.2.)

- **Partition Table**
  
  A contiguous sequence of real pages beginning at the real address specified by the PTCR contains the Partition Table.

- **Page Table**
  
  A contiguous sequence of real pages beginning at the real address specified by the first doubleword of the Partition Table Entry when HR=0 contains the Page Table.

6.7.5.1 Effective Address Space Structure for Radix-using Partitions

When Radix Tree translation is in use but translation is disabled (MSR$_{IR}$=0 or MSR$_{DR}$=0, as appropriate for the type of access), MSR$_{HV}$ selects between partition-scoped translation of the real mode guest real address, formed by treating EA$_{0:1}$ as 0b00, and hypervisor or ultravisor real mode (see Section 6.7.3). When Radix Tree translation is in use and translation is enabled, EA$_{0:1}$ together with MSR$_{HV}$ are used to select one of as many as three distinct Radix Trees to which to perform process-scoped translation, as a technique to make system calls and interrupts more efficient by avoiding the need to immediately change the contents of the PIDR and LPIDR. (See Figure 21 for an illustration of the mappings.) Since there's nothing to prevent a process from generating any address in the 64b EA space, the exceptional cases are defined as follows. When a quadrant of the EA space has no associated Radix Tree, access to it results in an Instruction Segment exception or Data Segment exception, as appropriate for the type of access. Similarly, reference to any portion of these quadrants or the real mode guest real address described above that is not mapped by a Radix Tree (versus mapped by an invalid entry) will cause an Instruction or Data Segment exception.

---

**Programming Note**

Note that the quadrant structure is only available to software running in 64b mode with address translation enabled. 32b software will only be able to access storage mapped by its own Radix Tree. When address translation is disabled and HV||PR=0b00, the EA accesses storage mapped into the guest real address space.

---

**Programming Note**

*Warning:* The functionality described in this section, e.g. directing most hypervisor interrupts to the LPIDR=0 translation tables, places great importance on the correctness of the format of and mappings in Partition Table Entry 0 and the tables it anchors. An error in any of these structures could have severe consequences including system checkstops and hangs.

---

**Programming Note**

The intent is that the PIDR and LPIDR contents indicate the process and partition on behalf of which execution is taking place. For example, when a guest process interrupts to the hypervisor, execution to service the interrupt will generally be on behalf of the guest partition. When execution changes to be purely managing hypervisor resources that are not directly tied to any partition, the hypervisor should set LPIDR to 0.

For guest and host applications, guest operating systems, and the hypervisor acting as an operating system (LPIDR=0), quadrant 0 (EA$_{0:1}$=0b00) is mapped by the Radix Tree for the application and quadrant 3 (EA$_{0:1}$=0b11) is mapped by the Radix Tree for the
direct supervisor of the application. Quadrants 1 and 2 have no associated Radix Tree for guest and host applications and guest operating systems, but hold echoes of quadrants 0 and 3 for the hypervisor acting as an operating system.

**Programming Note**

Outboard accelerators may commonly be limited to accessing quadrants 0 and 3 as a matter of platform architecture. In such platforms, references to quadrants 1 and 2 may be regarded as errors.

For the hypervisor acting as a hypervisor (LPIDR ≠ 0), quadrant 3 is as described above. Quadrant 1 (EA0:1=0b01) is mapped by the Radix Tree for the guest application and quadrant 2 (EA0:1=0b10) is mapped by the Radix Tree for the guest operating system, one of which experienced a hypervisor interrupt or performed a system call to the hypervisor. Quadrant 0 has no associated Radix Tree.

When MSRHV=1 and EA0:1=0b00 or 0b11 (and the quadrant is mapped by a Radix Tree), only process-scoped translation is performed. When MSRHV=0 and MSRIR/DR=0, only partition-scoped translation is performed. Otherwise, nested process- and partition-scoped translations are performed.

6.7.6 In-Memory Tables

The In-Memory Tables are used to find the tables that are used in the actual translation process for the partition and process that are executing. They enable hardware, including accelerator hardware separate and distinct from the Power ISA processors in the platform, to perform the translation process largely without software intervention. Description of the In-Memory Table structure follows. Hardware may cache the contents of the In-Memory Tables. Variants of tlbie[1] may be used to manage the caching even though the In-Memory Table contents are not cached in the TLB. When “thread” is used in descriptions of the ordering of accesses and operations (e.g. invalidations) related to translation cache management, it should be understood to include execution streams in accelerators unless otherwise stated or obvious from context.

When an address in the In-Memory Table structure is specified to be a virtual or guest real address, the access to that address is considered to be performed with translation on. For a host using HPT translation, a base page size is specified for each such access to be used in the HPT search. The hypervisor can override the Segment Table Page Size in the Process Table Entry (PRTE, see Figure 24) using LPCRSL. The base page size for the Process Table (PATPRTPS) can be safely altered by the hypervisor since the OS does not have direct access to the Partition Table Entry. All accesses to the In-Memory Tables, the Segment Tables, and the guest Radix Tables that are performed with translation on, including for instruction address translation, are data accesses performed as if MSRPR=0 for the purpose of determining storage protection, although instruction side translation exceptions cause [H]ISI. (A specific example of the implications of this is that tables used to translate instruction fetches may be located in guarded or no-execute storage.)

**Programming Note**

The descriptors in the entries in this section and its subsections contain addresses that are properly aligned so that no shifting is required. For example, the minimum size of the Partition Table is 4KB, so PATB has the thirteenth least significant address bit as its least significant bit. To construct the real address for a 4KB table, 12 zeros are appended on the right, and an appropriate number of address bits are removed from the left to match the real address size (m) supported by the implementation. For an aligned 8K table, bit 51 of the PTCR would be disregarded, and 13 zeros would be appended.

6.7.6.1 Partition Table

The Partition Table Control Register (PTCR) is a 64-bit register that contains the host real address of the base
of the Partition Table and specifies its size. Software must ensure that the contents of the PTCR are the same for all processors in the system prior to enabling translation or transferring control to a partition.

<tr>
<td>59:63</td>
<td>PATS</td>
<td>Partition Table Size=$2^{12+PATS}$ PATS≤24</td>
</tr>
</tbody>
</table>

All other fields are reserved.

**Programming Note**

If it becomes necessary to shrink the Partition Table or to change PATB to point to a table that is not identical to the existing one, it is necessary to issue `tlbie` with RIC=2 to invalidate caching of outdated In-Memory Table Entries.

The Partition Table is composed of a pair of double-words per partition. The first doubleword indicates whether the partition uses HPT or Radix Tree translation and whether the partition is secure, and contains the base of the host’s translation table structure in host real memory. The first doubleword also contains the size of the table structure and the size of the Root Page Directory for a hypervisor using Radix Tree translation, or the base page size for the VRMA for Paravirtualized HPT translation. Additional details about the parameters for HPT translation follow.

The HTABORG field contains the high-order 42 bits of the 60-bit real address of the Page Table. The Page Table is thus constrained to lie on a $2^{18}$ byte (256 KB) boundary. At least 11 bits from the hash function (see Figure 31) are used to index into the Page Table. The minimum size Page Table is 256 KB ($2^{11}$ PTEGs of 128 bytes each).

The Page Table can be any size $2^n$ bytes where $18 \leq n \leq 46$. As the table size is increased, more bits are used from the hash to index into the table.

The HTABSIZE field contains an integer giving the number of bits (in addition to the minimum of 11 bits) from the hash that are used in the Page Table index. This number must not exceed 28. HTABSIZE is used to generate a mask of the form 0b00...011...1, which is a string of 28 - HTABSIZE 0-bits followed by a string of HTABSIZE 1-bits. The 1-bits determine which additional bits (beyond the minimum of 11) from the hash are used in the index (see Figure 31).

On implementations that support a real address size of only $m$ bits, $m<60$, bits 0:59-$m$ of the HTABORG field are treated as reserved bits, and software must set them to zeros.

**Example:**

Suppose that the Page Table is 16,384 ($2^{14}$) 128-byte PTEGs, for a total size of $2^{21}$ bytes (2 MB). A 14-bit index is required. Eleven bits are provided from the hash to start with, so 3 additional bits from the hash must be selected. Thus the value in HTABSIZE must be 3. The HPT may begin on any 256KB boundary.
All other fields are reserved.

Figure 23. Partition Table Entry Variants

The second doubleword of the Partition Table Entry contains the base of the partition’s Process Table, which is a guest real address (or effective address when effective LPID=0) for radix hypervisor and virtual address for HPT hypervisor, and the size of the Process Table. The Process Table is assumed to be aligned. Software that uses Radix Tree translation must set the low order PRTS bits of PRTB to 0s. When Segment Tables are provided, the Process Table base address is specified as a VSID with the assumption that the Process Table is located at zero offset in the segment, and also includes the base page size used for the HPT search, with the rest of the implied segment descriptor being B=0b01 (1TB segment), Ks=Kp=0, N=0, C=0, and virtual page class key protection does not apply. The Partition Table Entry variants are illustrated in Figure 23. Note that a configuration with HR=1 for a non-zero LPID and HR=0 for LPID=0 is considered an unsupported MMU configuration because it would attempt to perform HPT translation in quadrants 0 and 3 when MSRHV=1. In addition, LPID=0 with Radix Tree translation is an unsupported MMU configuration when MSRHV=0.

6.7.6.2 Process Table

The Process Table is composed of a quadword Process Table Entry per process in the partition. For partitions that use HPT translation, the Process Table Entry contains a Segment Table descriptor, which is composed of the origin of the Segment Table in virtual address space, the size of the segment and pages that hold the table, the size of the table, and a valid bit that is turned off while changes are made to the entry and Segment Table. The translation of the base address of the Segment Table is completed using an implied segment descriptor with Ks=Kp=0, N=0, C=0, and virtual page class key protection does not apply. For partitions that use Radix Tree translation, the Process Table Entry contains a Radix Tree root descriptor. When running on a host that uses Radix Tree translation, there are two cases. When effLPID=0, the RPDB is a host.
real address. Otherwise, the address is a guest real address and must undergo translation using the hypervisor’s Radix Tree for the partition (i.e. the “partition-scoped” tables, as defined later).

The architecture defines segment translation and two types of page translation. Segment translation is paired with HPT translation. The other supported “pairing” is two level Radix Tree translation. Either of these pairings can be used to translate an effective address into a host real address. The In-Memory Tables described above determine the translation mode used by a partition, as well as the locations of the Page Tables and Segment Tables, and the base page size for the Segment Tables. When MSR_{hv}=1 and/or MSR_{ir}=0 or MSR_{dr}=0 (as appropriate for the type of access), the steps taken for a given mode vary. See Sections 6.7.11.3 and 6.7.11.4 for details.

The pairing of Segment translation and Hashed Page Table (HPT) translation applies Segment translation to an effective address to produce a virtual address as described in Section 6.7.8, and HPT translation to the virtual address to produce a host real address as described in Section 6.7.9. Segment translations can be established by both the guest and the hypervisor, but the HPT translation is always managed by the hypervisor with the guest typically giving direction via system calls to the hypervisor in a paravirtualization relationship. This mode is commonly referred to as Paravirtualized HPT translation. The segment translation is managed on a per-process (“process-scoped”) basis, mapping a smaller effective address space into a large “partition-scoped” virtual address space, where the segment can be used as a shared memory object. There is also the possibility of thread-unique mappings. In the basic version of HPT translation, storage exceptions are directed to the operating system, which in turn issues system calls to the hypervisor. When Virtualized Partition Memory is enabled, storage exceptions are directed to the hypervisor, enabling a higher degree of memory overcommitment as the hypervisor transparently steals pages from the partition. Figure 25 gives an overview of the address translation process.

All other fields are reserved.

Figure 24. Process Table Entry Variants

6.7.7 Address Translation Overview

The effective address (EA) is the address generated by the hardware for an instruction fetch or for a data access. If address translation is enabled, this address is passed to the Address Translation mechanism, which attempts to convert the address to a real address which is then used to access storage. If the effective address cannot be translated, a storage exception (see Section 6.2) occurs.
In Paravirtualized HPT mode, the hypervisor also uses the segment/HPT pairing, and can create a process called an “adjunct”. To do so, it eliminates any potentially conflicting guest segment mappings and creates adjunct mappings prior to dispatching the adjunct.

In the other pairing, Radix Tree translation is used for both the process-scoped and partition-scoped mappings. This mode is sometimes referred to as nested Radix or Radix on Radix translation. Figure 26 gives an overview of the address translation process for Radix on Radix translation. Note that each level of the guest Radix Tree produces a guest real address that must itself undergo partition-scoped translation. See Figure 37 for a detailed illustration of the entire process.

Storage exceptions for process-scoped translation are directed to the operating system, and storage exceptions for partition-scoped translation are directed to the hypervisor. (In this categorization, single level translation is considered process-scoped translation except when VPM is active, in which case it is treated like partition-scoped translation.) As a result, for Radix on Radix translation, the hypervisor can use the partition-scoped mapping to limit the size of the guest real address space, and Virtualized Partition Memory is not necessary to enable a higher degree of memory over-commitment. If in Radix on Radix mode the guest real address is outside the range covered by the partition-scoped Radix Tree, the results are boundedly undefined.

The address specified in ASDR is the guest real address or VSID for which translation has most immediately failed except when the translation fails too early to produce that value. HDAR will generally contain the EA or lower VA bits for which translation has most immediately failed. For example, in the case of a Page Directory being paged out, the ASDR will contain the guest real address of the Page Directory Entry (down to bit 51), rather than the GRA of the datum being accessed. Exceptions may be manifest in unexpected ways. For example, an instruction fetch can fail to set a Change bit in the host PTE mapping the guest PTE. Similarly, the Reference bit update might fail for lack of write authority on the PTE.

Figure 25. Address translation overview

Figure 26. Address translation overview, Radix on Radix

Translation Lookaside Buffer

Conceptually, the Page Table is searched by the address relocation hardware to translate every reference. For performance reasons, the hardware usually
keeps a Translation Lookaside Buffer (TLB) that holds PTEs that have recently been used. The TLB is searched prior to searching the Page Table and, for Radix Tree Translation, prior to searching the Page Walk Cache. As a consequence, when software makes changes to the Page Table it must perform the appropriate TLB invalidate operations to maintain the consistency of the TLB with the Page Table (see Section 6.10). An implementation may associate each of its TLB entries with the partition for which the TLB entry was created, so that the entries can be retained while other partitions are executing.

**Programming Notes**

1. Page Table Entries may or may not be cached in a TLB.
2. It is possible that the hardware implements more than one TLB, such as one for data and one for instructions. In this case the size and shape of the TLBs may differ, as may the values contained therein.
3. Use the `tlbie` instruction to ensure that the TLB no longer contains a mapping for a particular page.

**Page Walk Cache**

For performance reasons, the hardware usually keeps a Page Walk Cache (PWC) that holds Page Directory Entries that represent partial tree traversals (one or more levels) from recent Radix Tree translations. The PWC is searched (perhaps iteratively, depending on the design) with the goal of skipping some of the storage accesses that would otherwise be needed to traverse the Radix Tree. The internal structures of the Radix Trees are considered to be managed separately from the final translations. When software changes this structure, it must perform appropriate invalidations to the PWC to maintain the consistency of the PWC with the Radix Tree (see Section 6.10). An implementation may associate each of its PWC entries with the partition for which the PWC entry was created, so that the entries can be retained while other partitions are executing.

**Programming Notes**

1. Page Directory Entries may or may not be cached in a PWC.
2. It is possible that the hardware implements more than one PWC, such as one for data and one for instructions. In this case the size and shape of the PWCs may differ, as may the values contained therein.
3. Use the `tlbie` instruction to ensure that the PWC no longer contains information describing a particular portion of a Radix Tree.

### 6.7.8 Segment Translation

Conversion of a 64-bit effective address to a virtual address is done by searching the Segment Lookaside Buffer (SLB) as shown in Figure 27. If no matching translation is found in the SLB, LPCR_UPRT=1, and either MSR_{hv}=0 or LPID=0, the Segment Table is searched. For implicit accesses, implicit segment descriptors are provided, as described elsewhere in this chapter.

**Figure 27. Translation of 64-bit effective address to 78 bit virtual address**

### 6.7.8.1 Segment Lookaside Buffer (SLB)

The Segment Lookaside Buffer (SLB) specifies the mapping between Effective Segment IDs (ESIDs) and Virtual Segment IDs (VSIDs). The number of SLB entries is implementation-dependent, except that all implementations provide at least 32 entries.

The first four entries, and when LPCR_UPRT=0 all of the entries, of the SLB are managed by software, using the instructions described in Section 6.9.3.2. See Chapter 12, “Synchronization Requirements for Context Alterations” on page 1333 for the rules that software must follow when updating the SLB.
**SLB Entry**

Each SLB entry (SLBE, sometimes referred to as a “segment descriptor”) maps one ESID to one VSID. Figure 28 shows the layout of an SLB entry.

<table>
<thead>

</tr>
</tbody>
</table>

All other fields are reserved. B_0 (SLBE_{37}) is treated as a reserved field.

**Figure 28. SLB Entry**

Instructions cannot be executed from a No-execute (N=1) segment.

Segments may contain a mixture of page sizes. The L and LP bits specify the base virtual page size for the segment. The SLB\_L\_LP encodings are those shown in Figure 29. The base virtual page size (also referred to as the “base page size”) is the smallest virtual page size that can be used to map a given access, and in most cases is the smallest virtual page size for the segment. (The exception is that multiple base virtual page sizes can occur within the same segment when the base page size specified for a given implicit access (e.g. of one segment table) does not match the base page size specified for another implicit access (e.g. of a different segment table or the process table) or for explicit accesses. References to the base page size for a segment will be understood not to preclude or functionally conflict with this possibility.) The base virtual page size is 2^b bytes. The actual virtual page size (also referred to as the “actual page size” or “virtual page size”) is specified by PTE_{L\_LP}.

<table>
<thead>
<tr>
<th>encoding</th>
<th>base page size</th>
</tr>
</thead>
<tbody>
<tr>
<td>0b000</td>
<td>4 KB</td>
</tr>
<tr>
<td>0b101</td>
<td>64 KB</td>
</tr>
</tbody>
</table>

Additional values\(^1\) \(2^b\) bytes, where \(b > 12\) and \(b\) may differ among encoding values

\(^1\) The “additional values” are implementation-dependent, as are the corresponding base virtual page sizes. Any values that are not supported by a given implementation are reserved in that implementation.

**Figure 29. Page Size Encodings**

For each SLB entry, software must ensure the following requirements are satisfied.

- \(L||L_P\) contains a value supported by the implementation.
- The base virtual page size selected by the \(L\) and \(L_P\) fields does not exceed the segment size selected by the \(B\) field.
- If \(s=40\), the following bits of the SLB entry contain 0s.
  - \(ESID_{24:35}\)
  - \(VSID_{38:49}\)

The bits in the above two items are ignored by the hardware.

The Class field of the SLBE is used in conjunction with the \textit{slbie}, \textit{slbieg}, and \textit{slbia} instructions (see Section 6.9.3.2). “Class” refers to a grouping of SLB entries and implementation-specific lookaside information so that only entries in a certain group need be invalidated and others might be preserved. The Class value assigned to an implementation-specific lookaside entry derived from an SLB entry must match the Class value of that SLB entry. The Class value assigned to an implementation-specific lookaside entry derived from real mode address “translation,” SLS address translation, or translations required to access the Segment Table Entry Group is 0.

Software must ensure that the SLB contains at most one entry that translates a given effective address, and that if the SLB contains an entry that translates a given effective address, then any previously existing translation of that effective address has been invalidated. An attempt to create an SLB entry that violates this requirement may cause a Machine Check.
6.7.8.2 SLB Search

When the hardware searches the SLB, all entries are tested for a match with the EA. For a match to exist, the following conditions must be satisfied for indicated fields in the SLBE.

- \( V=1 \)
- \( \text{ESID}_{0:63-s} = \text{EA}_{0:63-s} \), where the value of \( s \) is specified by the \( B \) field in the SLBE being tested

If no match is found, the search fails. If one match is found, the search succeeds. If more than one match is found, one of the matching entries is used as if it were the only matching entry, or a Machine Check occurs.

If the SLB search succeeds, the virtual address (VA) is formed from the EA and the matching SLB entry fields as follows.

\[
\text{VA} = \text{VSID}_{0:77-s} \parallel \text{EA}_{64-s:63}
\]

The Virtual Page Number (VPN) is bits 0:77-p of the virtual address. The value of \( p \) is the actual virtual page size specified by the PTE used to translate the virtual address (see Section 6.7.9.1). If \( \text{SLB}_N = 1 \), the \( N \) (No-execute) value used for the storage access is 1.

If the SLB search fails and the state is not such that a Segment Table search will be performed, a segment fault occurs. This is an Instruction Segment exception or a Data Segment exception, depending on whether the effective address is for an instruction fetch or for a data access.

6.7.8.3 Segment Table Description and Search

The Segment Table is an aligned structure composed of 16B segment descriptors organized into 128 byte Segment Table Entry Groups (STEGs). Let \( q = \text{STAB-SIZE}+12, \log_2(\text{size of the Segment Table}) \). The base of the Segment Table in virtual address space is \( \text{STABORG}_{0:77-q} \parallel 0^q \). Software must set the lower order \( q-12 \) bits of \( \text{STABORG} \) to 0s. Primary and secondary hashes are defined for 256MB and 1TB segments, each mapping the ESID to an STEG. The appropriate number (for the size of the Segment Table) of low order ESID bits (their inverse, for the secondary hash) directly select the STEG. The order of STEG specification in the following subsections is the preferred order for a serial search. Implementations may search the STEGs in parallel. If no match is found, a segment fault occurs. If a serial search is done, the search may stop when a match has been found. If more than one match is found, one of the matching entries is used as if it were the only matching entry.

### Programming Note

Class values should be assigned such that Class 0 is used for translations that are expected to be long-lived and Class 1 is used for translations that are expected to be short-lived. This assignment facilitates use of the `slbia` instruction, for which several IH values cause preferential invalidation of Class 1 SLB entries and lookaside information entries.

### Programming Note

It is permissible for software to replace the contents of a valid SLB entry without invalidating the translation specified by that entry provided the specified restrictions are followed. See Chapter 12 Note 10.

### Figure 30. Segment Table Entry

6.7.8.3.1 Primary Hash for 256MB Segment

The STEG is located at host VA \( \text{STABORG}_{0:77-q} \parallel \text{EA}_{43-q:35} \parallel 0b00000000 \).

Each of the 8 STEs are searched to find a valid entry (\( V=1, B=0b00 \)) that matches the ESID (\( \text{STE}_{\text{ESID}[0:35]} = \text{EA}_{0:35} \)) of the access being translated.

6.7.8.3.2 Primary Hash for 1TB Segment

The STEG is located at host VA \( \text{STABORG}_{0:77-q} \parallel \text{EA}_{31-q:23} \parallel 0b00000000 \).

Each of the 8 STEs are searched to find a valid entry (\( V=1, B=0b01 \)) that matches the ESID (\( \text{STE}_{\text{ESID}[0:23]} = \text{EA}_{0:23} \)) of the access being translated.

6.7.8.3.3 Secondary Hash for 256MB Segment

The STEG is located at host VA \( \text{STABORG}_{0:77-q} \parallel \sim\text{EA}_{43-q:35} \parallel 0b00000000 \).
Each of the 8 STEs are searched to find a valid entry (V=1, B=0b00) that matches the ESID (STE_ESID[0:35] = EA0:35) of the access being translated.

6.7.8.3.4 Secondary Hash for 1TB Segment

The STEG is located at host VA
STABORG0:77-q || ¬EA31-q:23 || 0b0000000.
Each of the 8 STEs are searched to find a valid entry (V=1, B=0b01) that matches the ESID (STE_ESID[0:23] = EA0:23) of the access being translated.

6.7.9 Hashed Page Table Translation

In Paravirtualized HPT mode, conversion of a 78-bit virtual address to a real address is done by searching the Page Table as shown in Figure 31.
Figure 31. Translation of 78-bit virtual address to 60-bit real address
### 6.7.9.1 Hashed Page Table

The Hashed Page Table (HTAB) is a variable-sized data structure that specifies the mapping between virtual page numbers and real page numbers, where the real page number of a real page is bits 0:47 of the address of the first byte in the real page. The HTAB's size can be any size $2^n$ bytes where $18 \leq n \leq 46$. The HTAB must be located in storage having the storage control attributes that are used for implicit accesses to it (see Section 6.7.3.4). The starting address must be a multiple of $2^{18}$ bytes.

The HTAB contains Page Table Entry Groups (PTEGs). A PTEG contains 8 Page Table Entries (PTEs) of 16 bytes each; each PTEG is thus 128 bytes long. PTEGs are entry points for searches of the Page Table.

See Section 6.10 for the rules that software must follow when updating the Page Table.

---

#### Programming Note

The Page Table must be treated as a hypervisor resource (see Chapter 2), and therefore must be placed in real storage to which only the hypervisor has write access. Moreover, the contents of the Page Table must be such that non-hypervisor software cannot modify storage that contains hypervisor programs or data.

### Page Table Entry

Each Page Table Entry (PTE) maps one VPN to one RPN. Figure 32 shows the layout of a PTE. This layout is independent of the Endian mode of the thread.

</tr>
<tr>
<td></td>
<td>0b11 - reserved</td>
<td></td>
</tr>
</tbody>
</table>

---

#### Programming Note

The AVA field omits the low-order 23 bits of the VA. These bits are not needed in the PTE, because the low-order $b$ of these bits are part of the byte offset into the virtual page and, if $b<23$, the high-order $23-b$ of these bits are always used in selecting the PTEGs to be searched (see Section 6.7.9.2).

A virtual page is mapped to a sequence of $2^{p-12}$ contiguous real pages such that the low-order $p-12$ bits of the real page number of the first real page in the sequence are 0s.

PTEL $L$ specify both a base virtual page size (henceforth referred to as the "base page size") and an actual virtual page size (henceforth referred to as the "actual page size" or "virtual page size"). The actual page size is the size of the virtual page mapped by the PTE. The base page size is the smallest actual page size that a segment can contain for explicit accesses or for a given implicit access, and plays a role in the placement of the PTE in the HPT.

If PTEL $L$=0, the base virtual page size and actual virtual page size are 4KB, and ARPN concatenated with LP (ARPN||LP) contains the page number of the real page that maps the virtual page described by the entry.

---

The H bit in the Page Table Entry should not be set to one unless the secondary Page Table search has been enabled.

---

Because the length of the Abbreviated Virtual Address (AVA) field is only 45 bits, on implementations of this version of the architecture the virtual address size cannot exceed 68 bits ($n \leq 68$). On implementations for which $n<68$, bits 0:67-$n$ of the AVA field must be zeros.

If $b<23$, the AVA field contains bits 10:54 of the VA. Otherwise bits 0:67-$b$ of the AVA field contain bits 10:77-$b$ of the VA, and bits 68-$b$:44 of the AVA field must be zero.

---

Because the length of the Abbreviated Virtual Address (AVA) field is only 45 bits, on implementations of this version of the architecture the virtual address size cannot exceed 68 bits ($n \leq 68$). On implementations for which $n<68$, bits 0:67-$n$ of the AVA field must be zeros.

If $b<23$, the AVA field contains bits 10:54 of the VA. Otherwise bits 0:67-$b$ of the AVA field contain bits 10:77-$b$ of the VA, and bits 68-$b$:44 of the AVA field must be zero.
If \( \text{PTEL}=1 \), the base page size and actual page size are specified by \( \text{PTE}_{LP} \). In this case, the contents of \( \text{PTE}_{LP} \) have the format shown in Figure 33. Bits labelled “r” are bits of the real page number. Bits labelled “z” specify the base page size and actual page size. The values of the “r” bits used to specify each size are implementation-dependent. The values of the “z” bits used to specify each size, along with all possible values of “r” bits in the LP field, must result in LP values distinct from other LP values for other sizes. Actual page sizes 4KB and 64KB are always supported; other actual page sizes are implementation-dependent. If \( \text{PTEL}=1 \), the actual page size must be greater than 4 KB. Which combinations of different base page size and actual page size are supported is implementation-dependent, except that the combination of a base page size of 4 KB with an actual page size of 64 KB is always supported.

The actual page size specified by a given \( \text{PTE}_{LP} \) format is at least \( 2^{12+8-(c)} \), where c is the number of r bits in the format.

### Programming Note

Implementations often have TLBs and implementation-specific lookaside buffers (e.g. ERATs) used to cache translations of recently used storage addresses. Mapping virtual storage to large pages may increase the effectiveness of such lookaside buffers, improving performance, because it is possible for such buffers to translate a larger range of addresses, reducing the frequency that the Page Table must be searched to translate an address.

Instructions cannot be executed from a No-execute (N=1) page.

## Page Table Size

The number of entries in the Page Table directly affects performance because it influences the hit ratio in the Page Table and thus the rate of page faults. If the table is too small, it is possible that not all the virtual pages that actually have real pages assigned can be mapped via the Page Table. This can happen if too many hash collisions occur and there are more than 16 entries for the same primary/secondary pair of PTEGs (when the secondary Page Table search is enabled) or more than 8 entries for the same primary PTEG (when the secondary Page Table search is disabled).

While this situation cannot be guaranteed not to occur for any size Page Table, making the Page Table larger than the minimum size (see Section 6.7.6.1) will reduce the frequency of occurrence of such collisions.

### Programming Note

If large pages are not used, it is recommended that the number of PTEGs in the Page Table be at least half the number of real pages to be accessed. For example, if the amount of real storage to be accessed is \( 2^{31} \) bytes (2 GB), then we have \( 2^{31-12}=2^{19} \) real pages. The minimum recommended Page Table size would be \( 2^{19} \) PTEGs, or \( 2^{25} \) bytes (32 MB).

### 6.7.9.2 Page Table Search

When the hardware searches the Page Table, the accesses are performed as described in Section 6.7.3.4.

An outline of the HTAB search process is shown in Figure 31. Up to two hash functions are used to locate a PTE that may translate the given virtual address.

1. A 39-bit hash value is computed from the VA. The value of s is the value specified in the SLBE that was used to generate the virtual address; the value of b is equal to \( \log_2(\text{base page size specified} \)
in the SLBE that was used to translate the address). **Primary Hash:**

If \( s = 28 \), the hash value is computed by Exclusive ORing \( VA_{11:49} \) with \( (11+b_0||VA_{50:77-b}) \)

If \( s = 40 \), the hash value is computed by Exclusive ORing the following three quantities: \( (VA_{24:37} ||VA_{38:77-b}) \), \( (0||VA_{0:37}) \), and \( (b-10||VA_{38:77-b}) \)

The 60-bit real address of a PTEG is formed by concatenating the following values:
- Bits 0:27 of the 39-bit appropriate primary or secondary hash value ANDed with the mask generated from bits 59:63 of the first doubleword of the Partition Table Entry (HTABSIZE) and then added to the value of bits 4:45 of the first doubleword of the Partition Table Entry (HTABORG).
- Bits 28:38 of the 39-bit hash value.
- Seven 0-bits.

This operation identifies a particular PTEG, called the “primary PTEG”, whose eight PTEs will be tested.

**Secondary Hash:**

If the secondary Page Table search is enabled \( (LPCR_{T}=0) \), perform the secondary hash function as follows; otherwise do not perform step 2 and proceed to step 3 below.

If \( s = 28 \), the hash value is computed by taking the ones complement of the Exclusive OR of \( VA_{11:49} \) with \( (11+b_0||VA_{50:77-b}) \)

If \( s = 40 \), the hash value is computed by taking the ones complement of the following three quantities: \( (VA_{24:37} ||VA_{38:77-b}) \), \( (0||VA_{0:37}) \), and \( (b-10||VA_{38:77-b}) \)

The 60-bit real address of a PTEG is formed by concatenating the following values:
- Bits 0:27 of the 39-bit appropriate primary or secondary hash value ANDed with the mask generated from bits 59:63 of the first doubleword of the Partition Table Entry (HTABSIZE) and then added to the value of bits 4:45 of the first doubleword of the Partition Table Entry (HTABORG).
- Bits 28:38 of the 39-bit hash value.
- Seven 0-bits.

This operation identifies the “secondary PTEG”.

**3. As many as 8 PTEs in the primary PTEG and, if the secondary Page Table search is enabled, 8 PTEs in the secondary PTEG are tested to determine if any translate the given virtual address.**

Let \( q = \min\{54, 77-b\} \). For a match to exist, the following conditions must be satisfied, where \( SLBE \) is the SLBE used to form the virtual address.
- \( PTE_H = 0 \) for the primary PTEG, 1 for the secondary PTEG
- \( PTE_V = 1 \)

### PTEs

- \( PTE_E = SLBE_E \)
- \( PTE_{AV}[0:q-10] = VA_{10:q} \)
- if \( b = 12 \) then
  - \( (PTE_L = 0) \) \( (PTE_{LP} \) specifies the 4KB base page size)  
  - else
  - \( (PTE_L = 1) \) \( (PTE_{LP} \) specifies the base page size specified by \( SLBE_{L||LP} \) )

If no match is found, the search fails. The result is a page fault -- a [Hypervisor] Instruction Storage exception or a [Hypervisor] Data Storage exception, depending on whether the effective address is for an instruction fetch or for a data access. If one match is found, the search succeeds. If more than one match is found, one of the matching entries is used as if it were the only matching entry, or a Machine Check occurs.

If the Page Table search succeeds, the real address \( RA \) is formed by concatenating the following values, where the \( p \) value is the \( \log_2 \) (actual page size specified by \( PTE_{LP} \)).
- three 0 bits
- bits 0:56-p of \( ARPN||LP \) from the matching PTE
- bits 64-p:63 of the effective address (the byte offset)

\[ RA = 0b000 || (ARPN || LP)_{0:56-p} || EA_{64-p:63} \]

A TLB entry may be created as a result of the successful HPT translation. Depending on the specific TLB implementation, the scope of the entry may be the base page size, the virtual page size, or any size in between. In the absence of a TLB, software would be required to create a PTE for each base page sized piece of storage within the virtual page. The number of PTEs actually created to map a virtual page will depend on the scopes supported for TLB entries, the access pattern, and the lifetime of the TLB entries. Hardware generally will not create more than one TLB entry to translate a given virtual address. Multiple matching TLB entries may be created only if the Page Table contains PTEs that map different-sized virtual pages that overlap in the virtual address space. If a TLB search finds multiple matching TLB entries created from such PTEs, one of the matching TLB entries is used as if it were the only matching entry, or a Machine Check occurs. Software should scrupulously avoid creating such mappings.
**Programming Note**

If PTE_L = 0, the actual page size (and base page size) are 4 KB. Otherwise the actual page size and base page size are specified by PTE_LP.

Since hardware searches the Page Table using a value of b equal to \( \log_2 \) (base page size specified in the SLBE that was used to translate the address) regardless of the actual page size, the hardware Page Table search will identify different PTEs for VAs in different 2^b-byte blocks of the virtual page if the actual page size is larger than the base page size. Therefore, there may need to be a valid PTE corresponding to each 2^b-byte block of the virtual page that is referenced. For an actual page size that is larger than \( 2^{23} \) (8 MB), the PTEAVA will differ among some or all of these PTEs. Depending on the Page Table size, some or all of these PTEs may be in the same PTEG. Any such PTEs that are in the same PTEG will differ in the value of PTE_H or PTEAVA or both.

All PTEs for the same virtual page should have the same values in the Page Protection, KEY, ARPN, WIMG, and N fields. A set of values from any one of the PTEs that maps the virtual page may be used for an access in the virtual page since lookaside buffer information may be used to translate the virtual address.

To avoid creating multiple matching PTEs, software should not create PTEs for each of two different virtual pages that overlap in the virtual address space. If the virtual page sizes differ, two virtual pages overlap if the values of virtual address bits 0:77-p for both virtual pages are the same, where \( 2^p \) is the actual virtual page size of the larger page.

**Programming Note**

Because a segment may contain pages of different sizes, the Page Table search uses the segment’s base page size (which is the same for all virtual pages in the segment).

- The value of b used when searching the Page Table to identify the PTEGs to be checked for a match is \( \log_2 \) (segment’s base page size).
- A PTE (in the selected PTEGs) satisfies the Page Table search only if the base page size specified in the PTE is equal to the segment’s base page size.

The matching PTE supplies the actual page size, \( 2^p \); this value of p is used in forming the real address.

A virtual page of \( 2^p \) bytes in a segment with a base page size of \( 2^b \) bytes may be mapped by as many as \( 2^{(p-b)} \) PTEs.

---

**Programming Note**

To obtain the best performance, Page Table Entries should be allocated beginning with the first empty entry in the primary PTEG, or with the first empty entry in the secondary PTEG if the primary PTEG is full and the secondary Page Table search is enabled (LPCR_TC=0).

In Paravirtualized HPT mode, the N (No-execute) value used for the storage access is the result of ORing the N bit from the matching PTE with the N bit from the SLB entry that was used to translate the effective address.

### 6.7.10 Radix Tree Translation

Radix Tree translation uses a nested set of tables to map storage with increasing granularity. Although there is no requirement for an individual table to have uniform content, Page Directories generally contain pointers to other Page Directories or Page Tables (Page Directory Entries, PDEs), while Page Tables are the leaf tables that contain PTEs. Each Page Directory Entry and Page Table Entry in the Radix Tree is 8 bytes long. A Radix Tree root descriptor (RTRD) specifies the size of the address being translated, the size of the root table, and its location. RTRDs appear in variants of the Partition and Process Table Entries. (See Figures 23 and 24.) The Root Page Directory Size (RPDS) is specified as \( \log_2 \) (number of entries in the table). That number of bits is taken from the most significant end of the portion of the address being translated, as an index to choose an element in the Root Page Directory. The entries in the Root Page Directory point to another page of entries, and give its size in the Next Level Size field, PDE_NLS. The most significant NLS bits are taken from the address to choose an entry in that table. The process continues until an entry is found that has its Leaf bit set, indicating it is a Page Table Entry. The base size of the page mapped by the PTE is determined by the number of bits remaining in the address after removing the bits used to select the Page Directory and Page Table Entries. An example with RPDS = 13 and PDE_NLS = 9 in each Page Directory is shown in Figure 34.

The sizes of table supported at each level of the Radix Tree, as well as the ultimate page sizes supported, are implementation specific with the following exceptions. Implementations must support two Radix Tree configurations that map 52 bit effective addresses: each starting with a 64KB root page size followed by 2 levels of 4KB tables, ending with either a 256 byte table or a 4KB table. The former produces a page size of 64KB and the latter a 4KB page size. In both cases, a leaf node in the next to last level of table produces a 2MB page size.
Figure 34. Four level Radix Tree walk translating a 52b EA with NLS=13 in the root PDE and NLS=9 in the other PDEs.

6.7.10.3 Nested Translation

When MSR_HV=0 and translation is enabled, each guest real address must undergo partition-scoped translation using the hypervisor’s Radix Tree for the partition. See Figure 37.
When nested translation is being performed, there is the potential for two different sets of protection settings and two different sets of storage attributes. For protection settings, the least permissive values take effect.

For read, write, and execute authority, each is controlled independently based on the least permissive setting of the two translation mechanisms (including all component authority mechanisms within each of them). The Guarded attribute is controlled by the process-scoped PTE. Mismatches of the Caching Inhibited attribute have the following behavior. If the process-scoped PTE specifies I=1 when the parti-
tion-scoped PTE specifies I=0, the result is I=0. The reverse mismatch raises a data storage or instruction storage exception, as appropriate for the access. The results of these rules are shown in Table 5. Together these rules can produce the WIMG=0b0011 state that any individual Att value cannot express.

Unless otherwise stated or obvious from context, references elsewhere in the Books to storage control attributes for nested Radix Tree translations apply to the result of combining the guest and host storage control attributes as specified above. For example, the restrictions on the types of storage that can be accessed by AMOs in Section 4.5 of Book II applies to the results of the combining.

#### Programming Note

The mismatched Caching Inhibited attribute in the lower left quadrant above is given defined behavior instead of excepting in order to support frame buffer emulation. For frame buffer emulation, the guest believes it is writing to a frame buffer (I=1) in address space that the hypervisor maps to normal memory (I=0).

Reference and Change bit recording is done in both the process-scoped and partition-scoped Page Table Entries. Recording is done as described in Section 6.7.12, “Reference and Change Recording”.

For performance reasons, the result of each walk of a Radix Tree may be cached in a TLB. Logically, the result of each walk is cached separately. For nested translation, the effective to guest real (process-scoped) translation may be cached, as well as the partition-scoped translation for each guest real address produced by the translation process. A minimum of two TLB accesses is required to complete a nested translation: one for the effective to guest real address and one for the guest real to host real address. (An implementation may optimize the process, as long as the optimization can be managed correctly using the `tlbie` instructions that software will use to manage the logical model.)

### 6.7.11 Translation Process

As previously described, in its most complicated form the translation process includes the following steps:
- use of the PTCR to find the required Partition Table Entry
- use of the Partition Table Entry to find the partition-scoped Page Table
- use of the Partition Table Entry and the partition-scoped Page Table to find the required Process Table Entry
- use of the Process Table Entry and partition-scoped Page Table to find the required Segment Table Entry or walk the process-scoped Page Table (i.e. translate the effective address to a virtual or guest real address), and
- use of the partition-scoped Page Table to translate the virtual or guest real address.

Depending on the translation mode and process state, some of these steps may be skipped. The following subsections enumerate the cases and explain the steps in more detail.

#### 6.7.11.1 Fully-Qualified Address

The storage control facilities enable hardware to perform the entire translation process given a “fully-qualified address” and context that makes it a unique input. In addition to its normal use, the term “effective address” is sometimes used as shorthand for the fully-qualified address, and the architecture should be read with this possibility in mind. The following are the components of the fully-qualified address.

- effLPID
- effPID
- EA

The additional context required to perform a translation or match a cached translation may include the following.
- PATEHR (selected using the value in LPIDR, not effLPID)
- MSR_{HV PR IR DR}

The translation mode is selected by the Host Radix bit found in the Partition Table Entry. The Host Radix bit indicates whether the partition is using HPT or Radix Tree translation. Given the overall process, MSR_{HV PR IR DR} determines where and how the process is entered.

#### 6.7.11.2 Finding the Page Tables

[The following description assumes that no legacy mode is active, i.e. LPCRUPRT=1.] The components of the fully-qualified address are used to determine the table(s) used in the translation process. The effective LPID and effective PID are used to find the appropriate Page Table base address(es) using the In-Memory Table structures. Some types of trans-
lation use process-scoped Page Tables, some use partition-scoped Page Tables, and some use both.

Process-scoped table descriptors are found in the Process Tables as follows. The Partition Table Entry (PATE) host real address is calculated by adding the Partition Table Base Address (PATB)\(^{[120]}\) in the PTCR with 16 times the effective LPID. The second doubleword of the entry contains the base address of the Process Table for the partition. The Process Table is assumed to be aligned in effective \((HR=1, effLPID=0)\), virtual, or guest real address space. The Process Table Entry (PRTE) host real address is calculated by ORing the Process Table Base Address (PRTB)\(^{[400]}\) for an HPT host and PRTB\(^{[120]}\) for a radix host) in the PATE with 16 times the effective PID and then performing partition-scoped translation. (If the table is not aligned or is not large enough to support the PID value, an unreported error will most likely result.) The Process Table Entry at that location contains a process-scoped table base address, which is a guest real address for a radix guest \((HV=0)\), a host real address for a radix host \((HV=1)\), or a virtual address (all cases using HPT translation). The virtual or guest real address must be translated via the appropriate partition-scoped table.

### Programming Note

The guest real or virtual address of the Process Table, for a radix or HPT guest, respectively, may be set via an hcall. The radix guest may choose to map the Process Table into its own effective address space. These matters are not visible to the architecture.

### Programming Note

Note that the sole purpose of partition-scoped Page Table descriptor when LPID=0 for a radix host is to translate the effective addresses of the Process Table Entries for LPID=0. (If the Process Table Base address for LPID=0 was a real address, the Process Table would have to be in contiguous real storage.) This descriptor will commonly be the same as the descriptor found in the LPID=0, PID=0 Process Table Entry, both pointing to the hypervisor’s own page trable, but it may be set up to point to a table used solely to translate the addresses of Process Table Entries.

Partition-scoped Page Table descriptors are found in the Partition Table as follows. The Partition Table Base Address is found in the PTCR. The effective LPID (times 16 bytes per partition) is used to index off the Partition Table Base Address to find the appropriate Partition Table Entry. The first doubleword of the entry contains the base address of the Page Table.

### 6.7.11.3 Obtaining Host Real Address, Radix on Radix

The following cases exist.
- Guest access to quadrant 0 with translation on: process-scoped translation is performed on LPIDR||PIDR||EA, with the result subject to partition-scoped translation with effective LPID=LPIDR.
- Guest access to quadrant 3 with translation on: process-scoped translation is performed on LPIDR||0||EA, with the result subject to partition-scoped translation with effective LPID=LPIDR.
- Hypervisor access to quadrant 1 with translation on: process-scoped translation is performed on LPIDR||PIDR||EA, with the result subject to partition-scoped translation with effective LPID=LPIDR.
- Hypervisor access to quadrant 2 with translation on: process-scoped translation is performed on LPIDR||0||EA, with the result subject to partition-scoped translation with effective LPID=LPIDR.
- Guest OS access with translation off: partition-scoped translation is performed with effective LPID = LPIDR.
- Hypervisor or host application access to quadrant 0 with translation on: process-scoped translation is performed on 0||PIDR||EA.
- Hypervisor or host application access to quadrant 3 with translation on: process-scoped translation is performed with 0||0||EA.
- Hypervisor or ultravisor real mode access: subject to EA 0 and either HRMOR or URMOR, as described in Section 6.7.3.1.
6.7.11.4 Obtaining Host Real Address, HPT

There are two scenarios for Paravirtualized HPT translation. The first is the legacy scenario with a native HPT hypervisor. The second scenario is for a Radix Tree translation hypervisor providing a Paravirtualized HPT environment for the guest. In this latter scenario, the LPID=0 Partition Table Entry will have HR=1. For both scenarios the LPID value is always taken from LPIDR and the PID value is always taken from PIDR, even when MSR_HV=1. In the latter scenario, the hypervisor will explicitly set LPIDR=0 when it wants to use its Radix Tree(s).

When using Paravirtualized HPT translation, the process-scoped Page Tables are replaced by Segment Tables, and the description in Section 6.7.11.2, “Finding the Page Tables” can be read with that substitution in mind. The process-scoped translation is the effective-to-virtual translation described in Section 6.7.8. In-Memory Table walks are processed via the LPID=LPIDR partition-scoped HPT.

As with the previous enumerations, this is done from a hardware point of view. As a result, it does not differentiate the software cases for which Segment translation should only be satisfied by bolted translations.

The following cases exist.

- Guest access with translation on: process-scoped translation is performed on LPIDR||PIDR||EA with the result subject to partition-scoped translation using parameters from the matching segment descriptor.
- Hypervisor or adjunct access with translation on and LPID=0: process-scoped translation, limited to an SLB search with no Segment Table walk, is performed on LPIDR||PIDR||EA, with the result subject to partition-scoped translation using parameters from the matching segment descriptor.
- Hypervisor or adjunct access with translation on and LPID=0: process-scoped translation (with Segment Table walk) is performed on LPIDR||PIDR||EA, with the result subject to partition-scoped translation using parameters from the matching segment descriptor.
- Guest OS access with translation off: subject to VPM, as described in Section 6.7.3.3.
- Hypervisor or ultravisor real mode access: subject to EA0 and either HRMOR or URMOR, as described in Section 6.7.3.1.

Figure 38. Radix on Radix translation, general case

Figure 39. Paravirtualized HPT translation

6.7.12 Reference and Change Recording

When operating in Paravirtualized HPT mode, Reference (R) and Change (C) bits are updated in any one of what could be multiple (because of the multiple base size PTEs mapping a virtual page) Page Table Entries that map the virtual page that is being accessed. When operating in Radix on Radix mode, Reference (R) and
Change (C) bits may be updated in multiple Page Table Entries that are accessed as part of the translation process. (For example, each access to a guest’s Page Directory or Page Table Entry potentially sets a Reference bit in the partition-scoped table mapping it.) If the storage operand of a Load or Store instruction crosses a virtual page boundary, the accesses to the components of the operand in each page are treated as separate and independent accesses to each of the pages for the purpose of setting the Reference and Change bits.

For Radix Tree translation, hardware attempts to set the Reference and Change bits atomically, as though the PTE was read to perform the translation using a Load And Reserve instruction, and conditional on the translation being valid and correct (and on the existence of the reservation), the appropriate bit(s) are set as though with a Store Conditional instruction. ("as though" indicates that the reservation(s) held for this purpose are distinct from one another and from the reservation established by a Load And Reserve instruction.) If hardware is unable to set the bit(s) atomically, a [Hypervisor] Data Storage or [Hypervisor] Instruction Storage interrupt will be caused. For HPT translation, hardware sets the Reference and Change bits as though the PTE was read to perform the update using a (simple) Load instruction and the appropriate bit(s) are set as though with a (simple) Store instruction.

For both kinds of translation, setting the bits need not be atomic with respect to performing the access that causes the bits to be updated. The Reference bit must contain 1 in order to load from the corresponding page. The Change bit must contain 1 in order to store to the corresponding page.

**Programming Note**

The interrupt indicates to software that it must set the appropriate bit(s) itself. Note that an instruction fetch can cause a Change bit to be set, for example in the host Page Table Entry that maps the guest Page Table Entry if the instruction fetch causes the Reference bit to be set in the guest Page Table Entry.

**Programming Note**

In nested Radix Tree translation, as many as three Change bits may be set: in the process-scoped and partition-scoped PTEs for the access itself, and in the partition-scoped PTE that maps the process-scoped PTE. Similarly, a large number of Reference bits may be set, including for each partition-scoped PTE that maps a process-scoped PDE or PTE.

Reference and Change bits are set by the hardware as described below. An attempt to access storage may cause one or more of the bits to be set (as described below) even if the access is not performed. The bits are updated in the Page Table Entry if the new value would otherwise be different from the old value for the virtual page, as determined by examining either the Page Table Entry or any lookaside information for the virtual page (e.g., TLB) maintained by the hardware.

**Reference Bit**

The Reference bit is set to 1 if the corresponding access (load, store, implicit access, or instruction fetch) is required by the sequential execution model and is performed. Otherwise the Reference bit may be set to 1 if the corresponding access is attempted, either in-order or out-of-order, even if the attempt causes an exception, except that the Reference bit is not set to 1 for the access caused by an indexed Move Assist instruction for which the XER specifies a length of zero.

**Change Bit**

The Change bit is set to 1 if a Store instruction is executed and the store is performed or if an implicit update is performed. Otherwise in general
the Change bit may be set to 1 if a Store instruction is executed and the store is permitted by the storage protection mechanism and, if the Store instruction is executed out-of-order, the instruction would be required by the sequential execution model in the absence of the kinds of interrupts:

- system-caused interrupts (see Section 7.4 on page 1255)
- Floating-Point Enabled Exception type Program interrupts when the thread is in an Imprecise mode.

The only exceptions to the preceding statement are that the Change bit is not set to 1 if the instruction is a Store String Indexed instruction for which the XER specifies a length of zero, if the instruction is a Load Atomic or Store Atomic instruction with an invalid function code, or if the instruction is a Store Caching Inhibited instruction executed when MSRDR=1.

When the hardware updates the Reference and Change bits in a Page Table Entry, the accesses are performed as described in Section 6.7.3.4, “Storage Control Attributes for Implicit Storage Accesses” on page 1183. These Reference and Change bit updates are not necessarily immediately visible to software. Executing a sync instruction ensures that all Reference and Change bit updates associated with address translations that were performed, by the thread executing the sync instruction, before the sync instruction is executed will be performed with respect to that thread before the sync instruction’s memory barrier is created. There are additional requirements for synchronizing Reference and Change bit updates in multi-threaded systems; see Section 6.10, “Translation Table Update Synchronization Requirements” on page 1241.

---

**Programming Note**

A virtual page in a segment with a smaller base page size may be mapped by multiple PTEs. For each access of a virtual page, hardware may search the Page Table to update the R and C bits. If lookaside buffer information for the virtual page already indicates that all such bits to be set have already been set in a PTE that maps the virtual page, hardware need not make an update. Consider the following sequence of events:

1. A virtual page is mapped by 2 PTEs A and B and the R and C bits in both PTEs are 0.
2. A Load instruction accesses the virtual page and the R bit is updated in PTE A.
3. A Load instruction accesses the virtual page and the R bit is updated in PTE B.
4. A Store instruction accesses the virtual page and the C bit is updated in PTE B.
5. The virtual page is paged out. Software must examine both PTE A and B to get the state of the R and C bits for the virtual page.

Furthermore, if in event 2, PTE A was not found, a Data Storage interrupt or Hypervisor Data Storage interrupt may occur. Subsequently, if in event 3 or 4, PTE B was not found, a Data Storage interrupt or Hypervisor Data Storage interrupt may occur.

---

Even though the execution of a Store instruction causes the Change bit to be set to 1, the store might not be performed or might be only partially performed in cases such as the following.

- A Store Conditional instruction (stwcx. or stdcx.) or a Load Atomic or Store Atomic instruction (e.g. Fetch and Increment Bounded, Store Twin) is executed, but no store is performed.
- The Store instruction causes a Data Storage exception (all cases except Load Atomic or Store Atomic with an invalid function code, Store Caching Inhibited executed when MSRDR=1, EAO, or storage protection violation, which do not store and are not permitted to set the Change bit).
- The Store instruction causes an Alignment exception.
- The Page Table Entry that translates the virtual address of the storage operand is altered such that the new contents of the Page Table Entry preclude performing the store (e.g., the PTE is made invalid, or the PP bits are changed).

For example, when executing a Store instruction, the thread may search the Page Table for the purpose of setting the Change bit and then re-execute the instruction. When reexecuting the instruction, the thread may search the Page Table a second time. If the Page Table Entry has meanwhile been altered, by a program executing on another thread, the second search may obtain the new contents, which may preclude the store.

- A system-caused interrupt occurs before the store has been performed.
If software refers to a Page Table Entry when MSRDR=1 or MSR HV=0, the Reference and Change bits in the associated Page Table Entry are set as for ordinary loads and stores. See Section 6.10 for the rules software must follow when updating Reference and Change bits.

Figure 40 on page 1207 summarizes the rules for setting the Reference and Change bits. The table applies to each atomic storage reference. It should be read from the top down; the first line matching a given situation applies. For example, if stwcx fails due to both a storage protection violation and the lack of a reservation, the Change bit is not altered. The figure applies to PTE(s) that map instructions or storage operands of instructions. When Radix Tree translation is in use, Reference and Change bits are set in other, partition-scoped, PTEs as described earlier in this section.

In the figure, the “Load-type” instructions are the Load instructions described in Books I, II, and III, and the Cache Management instructions that are treated as Loads. The “Store-type” instructions are the Store instructions described in Books I, II, and III, and the Cache Management instructions that are treated as Stores. The Load Atomic and Store Atomic instructions are considered to be both loads and stores, and as a result could match “Load-type” and “Store-type” entries in the table. As a result, “Store-type” entries precede “Load-type” entries in the table so that AMOs match “Store-type” entries. The “ordinary” Load and Store instructions are those described in Books I, II, and III. “set” means “set to 1”.

Because the sync instruction is execution synchronizing, the set of Reference and Change bit updates that are performed with respect to the thread executing the sync instruction before the memory barrier is created includes all Reference and Change bit updates associated with instructions preceding the sync instruction.

Programming Note

Because the sync instruction is execution synchronizing, the set of Reference and Change bit updates that are performed with respect to the thread executing the sync instruction before the memory barrier is created includes all Reference and Change bit updates associated with instructions preceding the sync instruction.

*R means that it is acceptable to set the bit.

\(^1\) It is preferable not to set the bit.

\(^2\) If C is set, R is also set unless it is already set.

\(^3\) For Floating-Point Enabled Exception type Program interrupts, “imprecise” refers to the exception mode controlled by MSRFE0 FE1.

\(^4\) This case does not apply to the Touch instructions, because they do not cause a storage access.

Figure 40. Setting the Reference and Change bits
6.7.13 Storage Protection

The storage protection mechanism provides a means for selectively granting instruction fetch access, granting read access, granting write access, and prohibiting access to areas of storage based on a number of control criteria.

The operation of the storage protection mechanism depends on the value of one or more of the following.

- MSR bits HV, S, IR, DR, PR
- the key bits and N bit in the associated SLB entry
- the page protection bits, key bits, N bit, and G attribute in the associated PTE
- the AMR, IAMR, AMOR, and UAMOR
- the Secure Memory property

The storage protection mechanism consists of the Virtual Page Class Key Protection mechanism described in Section 6.7.13.1, the Basic Storage Protection mechanism described in Section 6.7.13.2 and Section 6.7.13.3, the Radix Tree Translation Storage Protection mechanism described in Section 6.7.13.4, and the Secure Memory Protection mechanism described in Section 6.7.13.5.

In order for a storage access to be permitted, it must be permitted by all of the mechanisms that apply to it. If SMFCTRLE=1, each storage access is subject to Secure Memory Protection independent of the translation mode of the access. In addition, each access is subject to other protection mechanisms depending on its translation mode, as listed below.

- **MSR might**=1 and address translation is disabled: Basic Storage Protection mechanism
- **HR**=0
  - access to instruction or data when address translation is enabled: Virtual Page Class Key Protection mechanism and Basic Storage Protection mechanism
  - all other cases (access to Process Table Entry or Segment Table Entry when address translation is enabled; access to instruction or data when MSR might=0 and address translation is disabled): Basic Storage Protection mechanism

**Programming Note**

Because the assumed K s and K p values are either 0 or irrelevant, these accesses are always permitted by the Basic Storage Protection mechanism.

- **HR**=1

- access to instruction or data when address translation is enabled and effLPID≠0: Radix Tree Translation Storage Protection mechanisms of both the process-scoped and partition-scoped PTEs, except that the Guarded attribute (which affects storage protection for instruction fetches) is determined solely by the process-scoped PTE

- access to instruction or data when address translation is enabled and effLPID=0: Radix Tree Translation Storage Protection mechanism of the process-scoped PTE

- all other cases (access to Process Table Entry when address translation is enabled; access to process-scoped PDE or process-scoped PTE when address translation is enabled and effLPID=0; access to instruction or data when MSR might=0 and address translation is disabled): Radix Tree Translation Storage Protection mechanism of the partition-scoped PTE

If an access associated with an instruction fetch is not permitted, an Instruction Storage exception or a Hypervisor Instruction Storage exception is generated. If an access associated with a data access is not permitted, a Data Storage exception or a Hypervisor Data Storage exception is generated.

A **protection domain** is a maximal range of effective addresses, virtual addresses, or guest real addresses for which variables related to storage protection can be independently specified (including by default, as in virtual real, hypervisor real, and ultravisor real addressing modes), or a maximal range of addresses, effective, virtual, or guest real, for which variables related to storage protection cannot be specified. Examples include: a segment, a virtual page (including for the Virtualized Real Mode Area), the Virtualized Real Mode Area, the effective address range 0:260-1 in hypervisor and ultravisor real addressing modes, and a maximal range of effective, virtual, or guest real addresses that cannot be mapped to real addresses. A **protection boundary** is a boundary between protection domains.

6.7.13.1 Virtual Page Class Key Protection

The Virtual Page Class Key Protection mechanism provides the means to assign virtual pages to one of 32 classes, and to modify data access permissions for each class by modifying the Authority Mask Register (AMR), shown in Figure 41, and to modify instruction access permissions for each class by modifying the Instruction Authority Mask Register (IAMR) shown in Figure 42.
Chapter 6. Storage Control

Version 3.1

1209

Authority Mask Register

The access mask for each class defines the access permissions that apply to loads and stores for which the virtual address is translated using a Page Table Entry that contains a Key field value equal to the class number. The access permissions associated with each class are defined as follows, where AMR2n and AMR2n+1 refer to the first and second bits of the access mask corresponding to class number n.

- A store is permitted if AMR2n=0b0; otherwise the store is not permitted.
- A load is permitted if AMR2n+1=0b0; otherwise the load is not permitted.

The AMR can be accessed using either SPR 13 or SPR 29. Access to the AMR using SPR 29 is privileged.

Programming Note

Because the AMR is part of the program context (if address translation is enabled), and because it is desirable for most application programmers not to have to understand the software synchronization requirements for context alterations (or the nuances of address translation and storage protection), operating systems should provide a system library program that application programs can use to modify the AMR.

Instruction Authority Mask Register

The access mask for each class defines the access permissions that apply to instruction fetches for which the virtual address is translated using a Page Table Entry that contains a Key field value equal to the class number. The access permission associated with each class is defined as follows, where IAMR2n+1 refers to the bit of the access mask corresponding to class number n.

- An instruction fetch is permitted if IAMR2n+1=0b0; otherwise the instruction fetch is not permitted.

Bit 0 of each key field is reserved.

Access to the IAMR is privileged.

The Authority Mask Override Register (AMOR) and the User Authority Mask Override Register (UAMOR), shown in Figure 43 and Figure 44 respectively, can be used to restrict modifications of the AMR. Also, the AMOR can be used to restrict modifications of the UAMOR and IAMR. Access to both the AMOR and UAMOR is privileged. The AMOR is a hypervisor resource.

Programming Note

If address translation is disabled for a given access, the access is not affected by the Virtual Page Class Key Protection mechanism even if the access is made in virtual real addressing mode.

Figure 41. Authority Mask Register (AMR)

Figure 42. Instruction Authority Mask Register (IAMR)

Figure 43. Authority Mask Override Register (AMOR)

Figure 44. User Authority Mask Override Register (UAMOR)

The bits of the AMOR and UAMOR are in 1-1 correspondence with the bits of the AMR (i.e., [U]AMORi corresponds to AMRi). The AMOR affects modifications of the AMR and UAMOR in privileged but non-hypervisor state; the UAMOR affects modifications of the AMR in problem state.

Similarly, the odd bits of the AMOR are in 1-1 correspondence with the odd bits of the IAMR (i.e.,
AMOR_{2j+1} corresponds to IAMR_{2j+1}). The AMOR affects modifications of the IAMR in privileged but non-hypervisor state; the IAMR cannot be accessed in problem state.

- When \textit{mtspr} specifying the AMR (using either SPR 13 or SPR 29) or the IAMR is executed in privileged non-hypervisor state, the AMOR is used as a mask that controls which bits of the resulting AMR or IAMR contents come from register RS and which AMR or IAMR bits are not modified.

- Similarly, when \textit{mtspr} specifying the AMR (using SPR 13) is executed in problem state, the UAMOR is used as a mask that controls which bits of the resulting AMR contents come from register RS and which AMR bits are not modified.

- When \textit{mtspr} specifying the UAMOR is executed in privileged non-hypervisor state, the AMOR is ANDed with the contents of register RS and the result is placed into the UAMOR; the AMOR thereby controls which bits of the resulting UAMOR contents come from register RS and which UAMOR bits are set to zero.

A complete description of these effects can be found in the description of the \textit{mtspr} instruction in Section 5.4.4.

Software must ensure that both bits of each even/odd bit pair of the AMOR contain the same value. — i.e., the contents of register RS for \textit{mtspr} specifying the AMOR must be such that (RS)_2n = (RS)_{2n+1} for every n in the range 0:31 — and likewise for the UAMOR. If this requirement is violated for the UAMOR the results of accessing the UAMOR (including implicitly by the hardware as described in the second item of the preceding list) are boundedly undefined; if the requirement is violated for the AMOR the results of accessing the AMOR (including implicitly by the hardware as described in the first and third items of the list) are undefined.

---

**Programming Note**

The preceding requirement permits designs to implement the AMOR and/or UAMOR as 32-bit registers — specifically, to implement only the even-numbered bits (or only the odd-numbered bits) of the register — in a manner such that the reduction, from the architecturally-required 64 bits to 32 bits, is not visible to (correct) software. This implementation technique saves space in the hardware. (A design that uses this technique does the appropriate “fan in/out” when the register is accessed, to provide the appearance, to (correct) software, of supporting all 64 bits of the register.)

Permitting designs to implement the [U]AMOR as 32-bit registers by virtue of the software requirement specified above, rather than by defining the [U]AMOR as 32-bit registers, permits the architecture to be extended in the future to support controlling modification of the “read access” AMR bits (the odd-numbered bits) independently from the “write access” AMR bits (the even-numbered bits), if that proves desirable. If this independent control does prove desirable, the only architecture change would be to eliminate the software requirement.

---

**Programming Note**

When modifying the AMOR and/or UAMOR, the hypervisor should ensure that the two registers are consistent with one another before giving control to a non-hypervisor program. In particular, the hypervisor should ensure that if AMOR_i=0 then UAMOR_i=0, for all i in the range 0:63. (Having AMOR_i=0 and UAMOR_i=1 would permit problem state programs, but not the operating system, to modify AMR bit i.)
The Virtual Page Class Key Protection mechanism replaces the Data Address Compare mechanism that was defined in versions of the architecture that precede Version 2.04 (e.g., the two facilities use some of the same resources, as described below). However, the Virtual Page Class Key Protection mechanism can be used to emulate the Data Address Compare mechanism. Moreover, programs that use the Data Address Compare mechanism can be modified in a manner such that they will work correctly both on implementations that comply with versions of the architecture that precede Version 2.04 (and hence implement the Data Address Compare mechanism) and on implementations that comply with Version 2.04 of the architecture or with any subsequent version (and hence instead implement the Virtual Page Class Key Protection mechanism). The technique takes advantage of the facts that the SPR number for privileged access to the AMR (29) is the same as the SPR number for the Data Address Compare mechanism's ACCR (Address Compare Control Register), that KEY4 occupies the same bit in the PTE as the Data Address Compare mechanism's AC (Address Compare) bit, and that the definition of ACCR62:63 is very similar to the definition of each even-odd pair of AMR bits. The technique is as follows, where PTE1 refers to doubleword 1 of the PTE.

- Set bits 2:3 and 62:63 of SPR 29 (which is either the ACCR or the AMR) to x, where x is the desired 2-bit value for controlling Data Address Compare matches, and set bits 0:1 to 0s.
- Set PTE1_54 (which is either the AC bit or KEY4) to the same value that the AC bit would be set to, and set PTE1_2:3 (which are either RPN bits, that correspond to a real address size larger than the size supported by any implementation that supports the Data Address Compare mechanism, or KEY0:1) and PTE1_52:53 (which are either reserved bits or KEY2:3) to 0s.
- Use PTEKEY values 0 and 1 only for purposes of emulating the Data Address Compare mechanism, except that PTEKEY value 0 may also be used for any virtual pages for which it is desired that the Virtual Page Class Key Protection mechanism permit all accesses. Do not use PTEKEY =31.
- When a Hypervisor Data Storage interrupt occurs, if HDSISR42=1 then ignore the interrupt for Cache Management instructions other than dcbz. (These instructions can cause a virtual page class key protection violation but cannot cause a Data Address Compare match.) Otherwise forward the interrupt to the operating system, which will treat the interrupt as if a Data Address Compare match had occurred. (Note: Cases for which it is undefined whether a Data Address Compare match occurs do not necessarily cause a virtual page class key protection violation.)

(Because privileged software can access the AMR using either SPR 13 or SPR 29, it might seem that, when SPR 13 was added to the architecture (in Version 2.06), SPR 29 should have been removed. SPR 29 is retained for two reasons: first, to avoid requiring privileged software to change to use the newer SPR number; and second, to retain the ability to emulate the Data Address Compare mechanism as described above.)
When address translation is enabled, the Basic Storage Protection mechanism is controlled by the following.

**Programming Note**

An example of the use of the AMOR (and UAMOR) is to support adjuncts (see Section 6.7.4, “Definitions”). The hypervisor could use KEY value j for all data virtual pages that only the adjunct must be able to access. Before dispatching the partition for the first time, the hypervisor would initialize the three registers as follows.

- **AMR**: all 0s except bits 2j and 2j+1, which would contain 1s
- **UAMOR**: all 0s
- **AMOR**: all 1s except bits 2j and 2j+1, which would contain 0s

Before dispatching the adjunct, the hypervisor would set UAMOR to all 0s, and would set the AMR to all 1s except bits 2j and 2j+1, which would be set to 0s. (Because the adjunct would run in problem state, there is no need for the hypervisor to modify the AMOR, and the adjunct cannot modify the UAMOR.) In addition, the hypervisor would prevent the partition from modifying or deleting PTEs that contain translations used by the adjunct.

(It may be desirable to avoid using KEY values 0, 1, and 31 for storage that only the adjunct can access, because these KEY values may be needed by the partition to emulate the Data Address Compare mechanism, as described above. Also, old software, that was written for an implementation that complies with a version of the architecture that precedes Version 2.04 (the version in which virtual page class keys were added), effectively uses KEY 0 for all virtual pages.)

**Programming Note**

Initialization of the UAMOR to all 0s, by the hypervisor before dispatching a partition for the first time, as described in the preceding Programming Note, permits operating systems (in partitions that run in a compatibility mode corresponding to Version 2.06 of the architecture or a subsequent version) to migrate gradually to supporting problem state access to the AMR — specifically, to avoid having to be changed immediately to modify the UAMOR and to save the AMR contents when an interrupt occurs from problem state. Relatedly, having the UAMOR contain all 0s while an application program is running protects old application programs that are “AMR-unaware”. In the absence of programming errors, such application programs would not attempt to read or modify the AMR. However, having the UAMOR contain all 0s protects such programs against modifying the AMR inadvertently.

Permitting an “AMR-unaware” application program to modify the AMR (inadvertently) is potentially harmful for the obvious reasons. (The program might set to 1 an AMR bit corresponding to accesses that are necessary in order for the program to work correctly.) Moreover, even for an operating system that includes support for problem state modification of the AMR, having the UAMOR contain all 0s allows the operating system to avoid saving and restoring the AMR for “AMR-unaware” application programs. Such an operating system would provide a system service program that allows an application program to declare itself to be “AMR-aware” — i.e., potentially to need to modify the AMR. When an application program invokes this service, the operating system would set the UAMOR to the non-zero value appropriate to the access authorities (load and/or store, for one or more key values) that the application program is allowed to modify, and thereafter would save and restore the AMR (and preserve the UAMOR) for this application program. (Having the UAMOR contain all 0s does not prevent an “AMR-unaware” program from reading the AMR, but inadvertent reading of the AMR is likely to be much less harmful than inadvertently modifying it.)

(For partitions that run in a compatibility mode corresponding to a version of the architecture that precedes Version 2.06, the PCR provides sufficient protection to application programs.)

### 6.7.13.2 Basic Storage Protection, Address Translation Enabled

When address translation is enabled, the Basic Storage Protection mechanism is controlled by the following.
MSR<sub>PR</sub>, which distinguishes between supervisor (privileged) state and problem state
K<sub>s</sub> and K<sub>p</sub>, the supervisor (privileged) state and problem state storage key bits in the SLB entry used to translate the effective address
PP, page protection bits 0:2 in the Page Table Entry used to translate the effective address
For instruction fetches only:
- the N (No-execute) value used for the access (see Sections 6.7.8.1 and 6.7.9.2)
- PTE<sub>G</sub>, the G (Guarded) bit in the Page Table Entry used to translate the effective address

Using the above values, the following rules are applied.
1. For an instruction fetch, the access is not permitted if the N value is 1 or if PTE<sub>G</sub>=1.
2. For any access except an instruction fetch that is not permitted by rule 1, a “Key” value is computed using the following formula:

   \[ \text{Key} = (K_p \& \text{MSR}_{PR}) \mid (K_s \& \neg \text{MSR}_{PR}) \]

   Using the computed Key, Figure 45 is applied. An instruction fetch is permitted for any entry in the figure except “no access”. A load is permitted for any entry except “no access”. A store is permitted only for entries with “read/write”.

All PP encodings not shown above are reserved. The results of using reserved PP encodings are boundedly undefined.

Figure 45. PP bit protection states, address translation enabled

6.7.13.3 Basic Storage Protection, Address Translation Disabled

When address translation is disabled, the Basic Storage Protection mechanism is controlled by MSR<sub>HV</sub>, which (when MSR<sub>PR</sub>=0) distinguishes between hypervisor state and privileged non-hypervisor state (see Chapter 2 and Section 6.7.3, “Ultravisor Real, Hypervisor Real, and Virtual Real Addressing Modes”). The following rules apply:

1. If MSR<sub>HV</sub>=0, access authority is determined as described in Section 6.7.3.3.
2. If MSR<sub>HV</sub>=1, the access is permitted.

6.7.13.4 Radix Tree Translation Storage Protection

For Radix Tree translation, an attempt to fetch instructions from Guarded storage is a storage protection violation. In all other respects, the storage protection mechanism for Radix Tree translation is completely different from what is provided for HPT translation. EAA<sub>1:3</sub> provide control over read, read/write, and execute access if the process has the appropriate privilege. EAA<sub>0</sub>, together with key 0 in the AMR or IAMR, provide three protection configurations for process-scoped translation: (1) a mode that gives equivalent access to privileged and problem state processes, (2) a mode that gives access only to problem state, and (3) a mode that gives access only to privileged processes. (Note that privileged includes hypervisor privileged.) For partition-scoped translation, including translation of table entry addresses, either value of EAA<sub>0</sub> permits the access. See Figure 36 and Figure 46 for details. The choice of whether to limit access to problem state for process-scoped protection of privileged read and write is determined by key 0 of the AMR. When bit 0 is 0, the privileged bit in the PTE is ignored for a privileged store. When bit 0 is 1, the privileged bit must be 1 for a privileged store. Similarly when bit 1 is 0, the privileged bit in the PTE is ignored for a privileged load. When bit 1 is 1, the privileged bit must be 1 for a privileged load. The choice of whether to limit access to privileged state for process-scoped protection of execute is determined by key 0 of the IAMR. When bit 0 is 0, the privileged bit in the PTE is ignored for an attempt to execute the instruction in privileged state. When bit 1 is 1, the privileged bit must be 1 to execute the instruction in privileged state.
Secure Memory Protection

When SMFCCTRL\_E=1, Secure Memory Protection is enabled. Each location in main storage has a Secure Memory property mem\_SM. mem\_SM=1 indicates secure memory. mem\_SM=0 indicates ordinary memory. Generally, only secure partitions and the ultravisor may access secure memory for explicit and implicit accesses. The one exception is that the Partition Table is commonly located in secure memory, but may be accessed implicitly as part of the translation process for software running with MSR\_P=0. The granularity and method with which main storage is mapped for the Secure Memory property is implementation specific.

For each kind of access to a host real address that can cause a violation of Basic or Radix Tree Translation Storage Protection, a Secure Memory Protection exception is reported by the same type of interrupt as its Basic or Radix Tree Translation Storage Protection counterpart, except setting [H]DSISR or [H]SRR1 bit 43 instead of 36, as follows. For HPT translation, the exception is reported as an ISI or DSI if the thread is in hypervisor state, or if the thread is in non-hypervisor state when IR or DR is 1 for the appropriate type of access and VPM=0; otherwise as HISI or HDSI. For Radix Tree translation, the exception is reported as an ISI or DSI if effLPID=0; otherwise as HISI or HDSI. The same reporting approach is used for accesses which require translation but for which no Basic Storage Protection exception is possible. This includes accesses to the Segment Table Entry Group and Process Table Entry when HPT translation is in use.

In the preceding cases the host real address for the access is a result of address translation. A Secure Memory Protection exception can also be caused by accesses to a host real address that is not the result of address translation. (Such accesses cannot cause a violation of Basic or Radix Tree Translation Storage Protection.) These additional cases are reported as follows. For a hypervisor real mode access the exception is reported as an ISI or DSI. For a process-scoped radix tree access for effLPID=0 the exception is reported as an ISI or DSI. For a PTEG access the exception is reported as an ISI or DSI if MSRHV PR=0b10; otherwise as HISI or HDSI. For a partition-scoped radix tree access the exception is reported as an HISI or HDSI unless effLPID=0, in which case the exception is reported as an ISI or DSI. These cases also set [H]DSISR or [H]SRR1 bit 43 to 1.

6.8 Storage Control Attributes

This section describes aspects of the storage control attributes that are relevant only to privileged software programmers. The rest of the description of storage
control attributes may be found in Section 1.6 of Book II and subsections.

6.8.1 Guarded Storage

Storage is said to be "well-behaved" if the corresponding real storage exists and is not defective, and if the effects of a single access to it are indistinguishable from the effects of multiple identical accesses to it. Data and instructions can be fetched out-of-order from well-behaved storage without causing undesired side effects.

Storage is said to be Guarded if any of the following conditions is satisfied:

- MSR bit IR or DR is 1 for instruction fetches or data accesses respectively, or MSR$_{HV}$=0, and either G=1 or Att=0b010 in the relevant Page Table Entry.
- MSR bit IR or DR is 0 for instruction fetches or data accesses respectively, MSR$_{HV}$=1, and the storage is specified by the Hypervisor Real Mode Storage Control facility to be treated as Guarded (see Section 6.7.3.2.1).

In general, storage that is not well-behaved should be Guarded. Because such storage may represent a control register on an I/O device or may include locations that do not exist, an out-of-order access to such storage may cause an I/O device to perform unintended operations or may result in a Machine Check.

The following rules apply to in-order execution of Load and Store instructions for which the first byte of the storage operand is in storage that is both Caching Inhibited and Guarded.

- **Load or Store** instruction that causes an atomic access
  
  If any portion of the storage operand has been accessed and an External, Decrementer, Hypervisor Decrementer, Performance Monitor, or Imprecise mode Floating-Point Enabled exception is pending, the instruction completes before the interrupt occurs.

- **Load or Store** instruction that causes an Alignment exception, or that causes a [Hypervisor] Data Storage exception for reasons other than Data Address Watchpoint match.

  The portion of the storage operand that is in Caching Inhibited and Guarded storage is not accessed.  

  (The corresponding rules for instructions that cause a Data Address Watchpoint match are given in Section 9.4.)

6.8.1.1 Out-of-Order Accesses to Guarded Storage

In general, Guarded storage is not accessed out-of-order. The only exceptions to this rule are the following.

**Load Instruction**

If a copy of any byte of the storage operand is in a cache then that byte may be accessed in the cache or in main storage.

**Instruction Fetch**

If MSR$_{HV}$=0b10 then an instruction may be fetched if any of the following conditions are met.

1. The instruction is in a cache. In this case it may be fetched from the cache or from main storage.
2. The instruction is in a real page from which an instruction has previously been fetched, except that if that previous fetch was based on condition 1 then the previously fetched instruction must have been in the instruction cache.
3. The instruction is in the same real page as an instruction that is required by the sequential execution model, or is in the real page immediately following such a page.

**Programming Note**

Software should ensure that only well-behaved storage is copied into a cache, either by accessing as Caching Inhibited (and Guarded) all storage that may not be well-behaved, or by accessing such storage as not Caching Inhibited (but Guarded) and referring only to cache blocks that are well-behaved.

If a real page contains instructions that will be executed when MSR$_{IR}$=0 and MSR$_{HV}$=1, software should ensure that this real page and the next real page contain only well-behaved storage (or that the Hypervisor Real Mode Storage Control facility specifies that this real page is not Guarded).

6.8.2 Storage Control Bits

When the thread is not in hypervisor or ultravisor real addressing mode, each storage access is performed under the control of the Page Table Entry used to translate the effective address. Each Page Table Entry contains storage control bits that specify the presence or absence of the corresponding storage control for all accesses translated by the entry as shown in Figure 47 and Figure 48. In the following description, references to individual WIMG bits apply to the corresponding Radix Att encoding, or to the result of combining the process-scoped and partition-scoped ATT encodings.
(see Section 6.7.10.3), except where otherwise stated or obvious from context.

1 Support for the 1 value of the W bit is optional. Implementations that do not support the 1 value treat the bit as reserved and assume its value to be 0.
2 Support for the 0 value of the M bit is optional, implementations that do not support the 0 value assume the value of the bit to be 1, and may either preserve the value of the bit or write it as 1.

M=1 always for Radix Tree translation

Figure 48. Storage control bits, Radix PTE

When the thread is not in hypervisor or ultravisor real addressing mode, instructions are not fetched from storage for which the G bit in the Page Table Entry is set to 1; see Section 6.7.13.

When the thread is in hypervisor or ultravisor real addressing mode, the storage control attributes are implicit; see Section 6.7.3.2.

In Sections 6.8.2.1 and 6.8.2.2, “access” includes accesses that are performed out-of-order, and references to W, I, M, and G bits include the values of those bits that are implied when the thread is in hypervisor or ultravisor real addressing mode.

---

**Programming Note**

In a system consisting of only a single-threaded processor which has caches, correct coherent execution does not require storage to be accessed as Memory Coherence Required, and accessing storage as not Memory Coherence Required may give better performance.

6.8.2.1 Storage Control Bit Restrictions

Process- and partition-scoped Att combinations that specify not Caching Inhibited for the process scope and Caching Inhibited for the partition scope are not permitted. See Table 5.

All combinations of W, I, M, and G values are permitted except those for which both W and I are 1.

---

**Programming Note**

If an application program requests both the Write Through Required and the Caching Inhibited attributes for a given storage location, the operating system should set the I bit to 1 and the W bit to 0.

At any given time, the value of the W bit must be the same for all accesses to a given real page.

At any given time, the value of the I bit must be the same for all accesses to a given real page.

6.8.2.2 Altering the Storage Control Bits

When changing the value of the W bit for a given real page from 0 to 1, software must ensure that no thread modifies any location in the page until after all copies of locations in the page that are considered to be modified in the data caches have been copied to main storage using `dcbst` or `dcbf` (or `dcbstps` or `dcbfps`).

When changing the value of the I bit for a given real page from 0 to 1, software must set the I bit to 1 and then flush all copies of locations in the page from the caches using `dcbf` (or `dcbfps`) and `icbi` before permitting any other accesses to the page. Note that similar cache management is required before using the Fixed-Point Load and Store Caching Inhibited instructions to access storage that has formerly been cached. (See Section 5.4.1 on page 1163.)
When changing the value of the M bit for a given real page, software must ensure that all data caches are consistent with main storage. The actions required to do this are system-dependent.

**Programming Note**

It is recommended that `dcbf` be used, rather than `dcbfl`, when changing the value of the I or W bit from 0 to 1. (`dcbfl` would have to be executed on all threads for which the contents of the data cache may be inconsistent with the new value of the bit, whereas, if the M bit for the page is 1, `dcbf` need be executed on only one thread in the system.)

Additional requirements for changing the storage control bits in the Page Table are given in Section 6.10.
6.9 Storage Control Instructions

6.9.1 Cache Management Instructions

This section describes aspects of cache management that are relevant only to privileged software programmers.

For a `dcbz` instruction that causes the target block to be newly established in the data cache without being fetched from main storage, the hardware need not verify that the associated real address is valid. The existence of a data cache block that is associated with an invalid real address (see Section 6.6) can cause a delayed Machine Check interrupt or a delayed Checkstop.

Each implementation provides an efficient means by which software can ensure that all blocks that are considered to be modified in the data cache have been copied to main storage before the thread enters any power conserving mode in which data cache contents are not maintained.

6.9.2 Synchronize Instruction

The Synchronize instruction is described in Section 4.6.3 of Book II, but only at the level required by an application programmer. This section describes properties of the instruction that are relevant only to operating system, hypervisor, and ultravisor software programmers.

The Synchronize instruction provides an ordering function for stores that are in set A of the memory barrier created by the Synchronize instruction, relative to data accesses caused by instructions that are executed on other threads after the occurrence of the interrupt that is caused by a `msgsndp`, `msgsnd`, or `msgsndu` instruction that follows the Synchronize instruction. The thread that is the target of the `msgsndp`, `msgsnd`, or `msgsndu` instruction is here called the "target thread".

- For `msgsndp`, and \( L = 0, 1, \) or \( 2 \) (or \( 4 \) or \( 5 \)) for the Synchronize instruction, the stores are performed with respect to the target thread before any data accesses caused by instructions that are executed on the target thread after the corresponding Directed Privileged Doorbell interrupt has occurred.

- For `msgsnd` or `msgsndu`, and \( L = 0 \) or \( 2 \) (or \( 4 \)) for the Synchronize instruction, the stores are performed with respect to any given other thread before any data accesses caused by instructions that are executed on the given other thread after a `msgsync` instruction is executed on that thread after the corresponding Directed Hypervisor or Ultravisor Doorbell interrupt has occurred on the target thread.

**Programming Note**

The `msgsync` instruction, which is needed when `msgsnd` or `msgsndu` is used, is not needed when `msgsndp` is used because `msgsndp` targets only threads on the same multi-threaded processor as the thread executing the `msgsndp`, while `msgsnd` and `msgsndu` can target any thread in the system. (If the target thread for `msgsnd` or `msgsndu` is on the same multi-threaded processor as the thread executing the `msgsnd` or `msgsndu`, in principle the `msgsync` can be omitted. This optimization is practical only when the `msgsnd/msgsndu` topology is appropriately constrained, however, because the Directed Hypervisor or Ultravisor Doorbell interrupt provides no indication of which thread executed the `msgsnd` or `msgsndu` that caused the interrupt, so there is no easy way for the interrupt handler to determine whether the `msgsync` can be omitted.) `msgsync` is not needed or defined in V. 2.07 for a similar reason: `msgsnd` in V. 2.07 can target only threads on the same multi-threaded processor as the thread executing the `msgsnd`.

The ordering done by `sync` (and `phwsync` and `ptesync`) provides the appearance of "causality" across a sequence of `msgsnd` (or `msgsndu`) instructions, as in the following example. "msgsnd->T1" means "msgsnd instruction targeting thread T1". "<DHDI 0>" means "occurrence of Directed Hypervisor Doorbell interrupt caused by msgsnd executed on T0". On T0, register r1 is assumed to contain the value 1.

```
| T0          | T1        | T2                          |
| std r1,X    | <DHDI 0>  | <DHDI 1>                    |
| sync        | msgsnd->T2 | msgsync                    |
| msgsnd->T1  |           | ld  r1,X                   |
```

In this example, T2's load from X must return 1.

**Programming Note**

Synchronize with \( L=1 \) (`lwsync`) or \( L=5 \) (`plwsync`) should not be used with `msgsnd` or `msgsndu`. (If used, it will not have the desired ordering effect.)
Another variant of the Synchronize instruction is described below. It is designated the Page Table Entry Synchronize instruction, and is specified by the extended mnemonic \texttt{ptesync} (equivalent to \texttt{sync} with \(L=2\)).

The \texttt{ptesync} instruction has all of the properties of \texttt{sync} with \(L=4\) and also the following additional properties.

- The memory barrier created by the \texttt{ptesync} instruction provides an ordering function for the storage accesses associated with all instructions that are executed by the thread executing the \texttt{ptesync} instruction and, as elements of set A, for all Reference and Change bit updates associated with additional address translations that were performed, by the thread executing the \texttt{ptesync} instruction, before the \texttt{ptesync} instruction is executed. The applicable pairs are all pairs \(a_i,b_j\) in which \(b_j\) is a data access and \(a_i\) is not an instruction fetch.

- The \texttt{ptesync} instruction causes all Reference and Change bit updates associated with address translations that were performed, by the thread executing the \texttt{ptesync} instruction, before the \texttt{ptesync} instruction is executed, to be performed with respect to that thread before the \texttt{ptesync} instruction’s memory barrier is created.

- The memory barrier created by the \texttt{ptesync} instruction provides an ordering function for all stores to the Partition Table, Process Tables, Segment Tables, Page Directories, and Page Tables caused by \texttt{Store} instructions preceding the \texttt{ptesync} instruction with respect to invalidations, of cached copies of information derived from these tables, caused by \texttt{slbieg}, \texttt{slbiag}, and \texttt{tlbie} instructions following the \texttt{ptesync} instruction. The memory barrier ensures that all searches of these tables by another thread, that are performed after an invalidation caused by such an \texttt{slbieg}, \texttt{slbiag}, or \texttt{tlbie} instruction has been performed with respect to the other thread and that implicitly load from the target location of such a store, will obtain the value stored (or a value stored subsequently).

In conjunction with the \texttt{tlbie} and \texttt{tlbsync} instructions, the \texttt{ptesync} instruction provides an ordering function for TLB invalidations and related storage accesses on other threads as described in the \texttt{tlbsync} instruction description on page 1240.

Similarly, in conjunction with the \texttt{slbieg} or \texttt{slbiag} and \texttt{slbsync} instructions, the \texttt{ptesync} instruction provides an ordering function for SLB invalidations and related storage accesses on other threads as described in the \texttt{slbsync} instruction description on page 1230.

delimiter Programming Note

The next bullet is sufficient to order the stores with respect to the invalidations on the thread executing the \texttt{ptesync} instruction. That bullet is also sufficient to provide the ordering with respect to invalidations caused by \texttt{slbie}, \texttt{slbia}, and \texttt{tlbie} instructions, which affect only the thread executing them.

The \texttt{ptesync} instruction provides an ordering function for all stores to the Partition Table, Process Tables, Segment Tables, Page Directories, and Page Tables caused by \texttt{Store} instructions preceding the \texttt{ptesync} instruction with respect to searches of these tables that are performed, by the thread executing the \texttt{ptesync} instruction, after the \texttt{ptesync} instruction completes. Executing a \texttt{ptesync} instruction ensures that all such searches that implicitly load from the target location of such a store will obtain the value stored (or a value stored subsequently). Also, the memory barrier created by the \texttt{ptesync} instruction ensures that all searches of these tables by any other thread, that are performed after a store in set B of the memory barrier has been performed with respect to the other thread and that implicitly load from the target location of such a store, will obtain the value stored (or a value stored subsequently).

Programming Note

For instructions following a \texttt{ptesync} instruction, the memory barrier need not order implicit storage accesses for purposes of address translation and reference and change recording.

The functions performed by the \texttt{ptesync} instruction may take a significant amount of time to complete, so this form of the instruction should be used only if the functions listed above are needed. Otherwise \texttt{sync} with \(L=0\) should be used (or \texttt{sync} with \(L=1\) or with \texttt{SC≠0}, or \texttt{eieio}, or \texttt{sync} with \(L=4\) or \(L=5\) if appropriate).

Section 6.10, “Translation Table Update Synchronization Requirements” on page 1241 gives examples of uses of \texttt{ptesync}.

6.9.3 Lookaside Buffer Management

All implementations have a Segment Lookaside Buffer (SLB). Independent of whether the executing partition operates in a mode that uses hardware SLB loading and bolting versus pure software loading (controlled by the value of LPCR\textsubscript{UPRT}), software is responsible for keeping the SLB current with the segment mapping for the process that is executing. Proper management of the SLB across context switches is described in programming notes.
For performance reasons, most implementations also cache other information that is used in address translation. These caches may include: a Translation Lookaside Buffer (TLB) which is a cache of recently used Page Table Entries (PTEs); a cache of recently used translations of effective addresses to real addresses; a Page Walk Cache for Radix Tree translation; caching of the In-Memory Tables; or any combination of these. Lookaside information, including the SLB, is managed using the instructions described in the subsections of this section unless additional requirements are provided in implementation-specific documentation.

To simplify lookaside buffer management, hardware will only perform speculative translation for the context that is executing, in particular using the current effective values of LPID and PID. Except when LPIDR=0, no translations will be created and cached speculatively when HR=0 and MSRHV=1. Furthermore, no translations will be created and cached speculatively in hypervisor or ultravisor real addressing mode. The limitation of speculative behavior in these situations is to cache a PATE when LPIDR is loaded and a PRTE when PIDR is loaded.

--- Programming Note ---

Speculative Segment Table walks are prohibited when MSRHV=1 and LPIDR=0 because adjacent translations are thread-specific and bolted.

Speculative Segment Table walks are allowed when MSRHV=1 and LPIDR=0 to improve performance for "bare metal" operating systems (operating systems that run in hypervisor state). Bare metal operating systems would use LPIDR=0.

Lookaside information derived from PTEs is not necessarily kept consistent with the Page Table. When software alters the contents of a PTE, in general it must also invalidate all corresponding TLB entries and implementation-specific lookaside information; exceptions to this rule are described in Section 6.10.1.2.

The effects of the slbie, slbieg, slbia, slbiag, and TLB Management instructions on address translations, as specified in Sections 6.9.3.2 for the SLB and 6.9.3.3 for the TLB, Page Walk Cache, and In-Memory Table caches, apply to all implementation-specific lookaside information that is used in address translation. Unless otherwise stated or obvious from context, references to SLB entry invalidation and TLB entry invalidation elsewhere in the Books apply also to invalidation of Page Walk Cache content, In-Memory Table cache content, and all implementation-specific lookaside information that is derived from SLB entries and PTEs, respectively.

All implementations provide a means by which software can invalidate all implementation-specific lookaside information that is derived from PTEs.

Implementation-specific lookaside information that contains translations of effective addresses to real addresses may include "translations" that apply in real addressing mode. Because such "translations" are affected by the contents of the LPCR, HRMOR, and URMOR, when software alters the (relevant) contents of these registers it must also invalidate the corresponding implementation-specific lookaside information. Software can invalidate all such lookaside information by using the slbia instruction with IH=0b0000. However, performance is likely to be better if other, appropriate, IH values are used to limit the amount of lookaside information that is invalidated.

All implementations that have such lookaside information provide a means by which software can invalidate all such lookaside information.

For simplicity, elsewhere in the Books it is assumed that the TLB exists.

--- Programming Note ---

Because the instructions used to manage TLBs, SLBs, Page Walk Caches, caches of Partition and Process Table Entries, and implementation-specific lookaside information may be changed in a future version of the architecture, it is recommended that software "encapsulate" their use into subroutines.

--- Programming Note ---

The function of all the instructions described in Sections 6.9.3.2 - 6.9.3.3 is independent of whether address translation is enabled or disabled.

For a discussion of software synchronization requirements when invalidating SLB and TLB entries, see Chapter 12.

6.9.3.1 Thread-Specific Segment Translations

It is necessary to provide thread-specific temporary ESID to VSID translations. These translations cannot be placed in valid entries in the Segment Table because the Segment Table has a process scope rather than a thread scope. Instead, software will use slbmte to install such translations in the SLB. All SLB entries created using slbmte are considered to be "software created." Software created entries will only translate accesses from the hardware thread by which they are installed. When LPCRUPRT=1, they are also considered to be "bolted." Each thread has the ability to bolt four entries.

6.9.3.2 SLB Management Instructions

The only functionality described in this section that is relevant to Radix Tree translation is the use of slbia to invalidate implementation-specific lookaside informa-
tion. The results of executing any other instruction in this section when HR=1 are boundedly undefined.

Software establishes translations in the SLB using `slb mte`. Care must be taken to avoid creating multiple effective-to-virtual translations for any given effective address. Software-created entries will remain in the SLB until invalidated using `slbie` or `slbia` (which also invalidate related implementation-specific lookaside information) or overwritten using `slb mte`. After updating a Segment Table Entry, software must use an `slbie` or `slbieg` instruction to remove lookaside information associated with the old contents of the entry. `slbie` may be used to invalidate software-created entries, but will not invalidate outboard translation caches. `slbieg` does not invalidate software-created entries, but, together with `slbieg`, is the only way to invalidate outboard translation caches. When taking a PID or LPID out of service with the intent of reusing it, software should use an `slbie` instruction to invalidate the old translation in the SLB, followed by an `slbieg` instruction to invalidate the translation remaining in the lookaside buffers.

### Programming Note

Accesses to a given SLB entry caused by the instructions described in this section obey the sequential execution model with respect to the contents of the entry and with respect to data dependencies on those contents. That is, if an instruction sequence contains two or more of these instructions, when the sequence has completed, the final contents of the SLB entry and of General Purpose Registers is as if the instructions had been executed in program order.

However, software synchronization is required in order to ensure that any alterations of the entry take effect correctly with respect to address translation; see Chapter 12.

<td>( \text{v} )</td>
</tr>
<tr>
<td>( \text{undefined} )</td>
<td>( \text{undefined} )</td>
</tr>
</tbody>
</table>

The operation performed by this instruction is based on the contents of register RB. The contents of this register are shown below.

```
<table>
<thead>
<tr>
<th>RB</th>
</tr>
</thead>
<tbody>
<tr>
<td>ESID</td>
</tr>
<tr>
<td>0</td>
</tr>
</tbody>
</table>
```

<table>
<thead>
<tr>
<th>RS0:31</th>
<th>PID</th>
</tr>
</thead>
<tbody>
<tr>
<td>RS32:63</td>
<td>LPID</td>
</tr>
<tr>

<td>ESID</td>
</tr>
<tr>
<td>RB36</td>
<td>Class</td>
</tr>
<tr>
<td>RB37:38</td>
<td>B</td>
</tr>
<tr>
<td>RB39:63</td>
<td>must be 0b0</td>
</tr>
</tbody>
</table>

Let the Effective Address (EA) be any EA for which \( \text{EA}0:35 = (RB)0:35 \). Let the class be \( (RB)36 \). Let the segment size be equal to the segment size specified in \( (RB)37:38 \); the allowed values of \( (RB)37:38 \), and the correspondence between the values and the segment size, are the same as for the B field in the SLBE (see Figure 28 on page 1191).

The class value and segment size must be the same as the class value and segment size in the SLB entry that translates the EA, or the values that were in the SLB entry that most recently translated the EA if the translation is no longer in the SLB; if these values are not the same, it is implementation-dependent whether the SLB entry (or implementation-dependent translation information) that translates the EA is invalidated, and the next paragraph need not apply.

If the SLB contains only a single entry that translates the EA, then that is the only SLB entry that is invalidated, except that it is implementation-dependent whether an implementation-specific lookaside entry for
a real mode address “translation” is invalidated. If the
SLB contains more than one such entry, then zero or
more such entries are invalidated, and similarly for any
implementation-specific lookaside information used in
address translation; additionally, a machine check may
occur.

SLB entries are invalidated by setting the V bit in the
entry to 0, and the remaining fields of the entry are set
to undefined values.

This instruction terminates any Segment Table walks
being performed on behalf of the thread that executes
it.

The hardware ignores the contents of RB listed below
and software must set them to 0s.
- \((RB)_{37}\)
- \((RB)_{39}\)
- \((RB)_{40:63}\)
- If \(s = 40\), \((RB)_{24:35}\)

If this instruction is executed in 32-bit mode, \((RB)_{0:31}\)
must be zeros.

This instruction is privileged.

**Special Registers Altered:**
- None

---

**Programming Note**

The reason the class value specified by `slbie` must
be the same as the Class value that is or was in the
relevant SLB entry is that the hardware may use
these values to optimize invalidation of implementa-
tion-specific lookaside information used in
address translation. If the value specified by `slbie`
differs from the value that is or was in the relevant
SLB entry, these optimizations may produce incor-
rect results. (An example of implementation-spe-
cific address translation lookaside information is
the set of recently used translations of effective
addresses to real addresses that some implement-
tions maintain in an Effective to Real Address
Translation (ERAT) lookaside buffer.) Note that
Radix Tree translations have no defined Class
value, so frequent translation mode transitions may
perform poorly under these optimizations.

When switching tasks in certain cases, it may be
advantageous to preserve some implementa-
tion-specific lookaside entries while invalidating
others. The `slbia` instruction specifying IH value
0b001 or 0b011 can be used for this purpose if SLB
class values are appropriately assigned, i.e., a
class value of 0 indicates that the entry should be
preserved and a class value of 1 indicates the entry
must be invalidated. Also, it is advantageous to
assign a class value of 1 to entries that need to be
invalidated via an `slbie` instruction while preserving
implementation-specific lookaside entries that are
derived from real mode address "translation," SLS
address translation, or translations required to
access the Segment Table Entry Group, since such
entries are assigned a class value of 0.

The B value in register RB may be needed for
invalidating ERAT entries corresponding to the
translation being invalidated.

When switching to execute an adjunct, a hypervisor
will disable translation and use `slbie` to be sure
there is no SLB entry mapping the effective
address space that will be used by the incoming
adjunct. It will then bolt an entry for the incoming
adjunct and transfer control to that adjunct. While
the thread is in hypervisor real addressing mode
and during adjunct execution, no speculative Seg-
ment Table walks will be performed.

---

Let the target PID be RS0:31. If the instruction is executed in hypervisor state, let the target LPID be RS32:63; otherwise let the target LPID be the contents of LPIDR. Let the Effective Address (EA) be any EA for which EA0:35 = (RB)0:35. Let the class be (RB)36. Let the segment size be equal to the segment size specified in (RB)37:38, the allowed values of (RB)37:38, and the correspondence between the values and the segment size, are the same as for the B field in the SLBE (see Figure 28 on page 1191).

Only SLBs for threads running on behalf of target_LPID and target_PID are searched. Software-created entries are not invalidated. The class value and segment size must be the same as the class value and segment size in the SLB entry that translates the EA, or the values that were in the SLB entry that most recently translated the EA if the translation is no longer in the SLB; if these values are not the same, it is implementation-dependent whether the SLB entry (or implementation-dependent translation information) that translates the EA is invalidated, and the next paragraph need not apply.

If the SLB contains only a single entry that translates the EA, then that is the only SLB entry that is invalidated, except that it is implementation-dependent whether an implementation-specific lookaside entry for a real mode address “translation” is invalidated. If the SLB contains more than one such entry, then zero or more such entries are invalidated, and similarly for any implementation-specific lookaside information used in address translation; additionally, a machine check may occur.

SLB entries are invalidated by setting the V bit in the entry to 0, and the remaining fields of the entry are set to undefined values.

The hardware ignores the contents of RB listed below and software must set them to 0s.
- (RB)37
- (RB)39
- (RB)40:63
- If s = 40, (RB)24:35
If this instruction is executed in 32-bit mode, (RB)0:31 must be zeros.

The operation performed by this instruction is ordered by the **eieio** (or **p[hi]w[ssyc]n** or **ptesync**) instruction with respect to a subsequent **slbsync** instruction executed by the thread executing the **slbieg** instruction. The operations caused by **slbieg** and **slbsync** are ordered by **eieio** as a fifth set of operations, which is independent of the other four sets that **eieio** orders.

This instruction is privileged except when LPCR_GTSE=0, making it hypervisor privileged.

**Special Registers Altered:**
None

**Programming Note**

**slbieg** does affect SLBs on other threads.
Power ISA™ III

1224

SLB Invalidate All

X-form

**Programming Note**

The reason the class value specified by `slbieg` must be the same as the Class value that is or was in the relevant SLB entry is that the hardware may use these values to optimize invalidation of implementation-specific lookaside information used in address translation. If the value specified by `slbieg` differs from the value that is or was in the relevant SLB entry, these optimizations may produce incorrect results. (An example of implementation-specific address translation lookaside information is the set of recently used translations of effective addresses to real addresses that some implementations maintain in an Effective to Real Address Translation (ERAT) lookaside buffer.) Note that Radix Tree translations have no defined Class value, so frequent translation mode transitions may perform poorly under these optimizations.

When switching tasks in certain cases, it may be advantageous to preserve some implementation-specific lookaside entries while invalidating others. The `slbia` instruction specifying IH value 0b001 or 0b011 can be used for this purpose if SLB class values are appropriately assigned, i.e., a class value of 0 indicates that the entry should be preserved and a class value of 1 indicates the entry must be invalidated. Also, it is advantageous to assign a class value of 1 to entries that need to be invalidated via an `slbieg` instruction while preserving implementation-specific lookaside entries that are derived from real mode address "translation," SLS address translation, or translations required to access the Segment Table Entry Group, since such entries are assigned a class value of 0.

**Programming Note**

The B value in register RB may be needed for invalidating ERAT entries corresponding to the translation being invalidated.

**Programming Note**

Use of `slbieg` to invalidate software-created segment descriptors is a programming error. The architecture requires that bolted entries not be invalidated by the instruction.

```
for each SLB entry except SLB entry 0
  SLBE_v 0
  all other fields of SLBE  undefined

 case (0b011):
  for each SLB entry such that SLBEClass = 1
  SLBE_v 0
  all other fields of SLBE  undefined

 case (0b100):
  for each SLB entry
  SLBE_v 0
  all other fields of SLBE  undefined

 case (0b111):
   slbia invalidates the contents of the SLB, and of implementation-specific lookaside information for effective to real address translations, based on the contents of the IH field as described below. SLB entries are invalidated by setting the V bit in the entry to 0. When an SLB entry is invalidated, the remaining fields of the entry are set to undefined values.

   In the description of the IH values, "implementation-specific lookaside information" is shorthand for "implementation-specific lookaside information for effective to real address translations, based on the contents of the IH field as described below. SLB entries are invalidated by setting the V bit in the entry to 0. When an SLB entry is invalidated, the remaining fields of the entry are set to undefined values.

   The reason the class value specified by `slbieg` must be the same as the Class value that is or was in the relevant SLB entry is that the hardware may use these values to optimize invalidation of implementation-specific lookaside information used in address translation. If the value specified by `slbieg` differs from the value that is or was in the relevant SLB entry, these optimizations may produce incorrect results. (An example of implementation-specific address translation lookaside information is the set of recently used translations of effective addresses to real addresses that some implementations maintain in an Effective to Real Address Translation (ERAT) lookaside buffer.) Note that Radix Tree translations have no defined Class value, so frequent translation mode transitions may perform poorly under these optimizations.

   When switching tasks in certain cases, it may be advantageous to preserve some implementation-specific lookaside entries while invalidating others. The `slbia` instruction specifying IH value 0b001 or 0b011 can be used for this purpose if SLB class values are appropriately assigned, i.e., a class value of 0 indicates that the entry should be preserved and a class value of 1 indicates the entry must be invalidated. Also, it is advantageous to assign a class value of 1 to entries that need to be invalidated via an `slbieg` instruction while preserving implementation-specific lookaside entries that are derived from real mode address "translation," SLS address translation, or translations required to access the Segment Table Entry Group, since such entries are assigned a class value of 0.

   The B value in register RB may be needed for invalidating ERAT entries corresponding to the translation being invalidated.

   Use of `slbieg` to invalidate software-created segment descriptors is a programming error. The architecture requires that bolted entries not be invalidated by the instruction.

   **Programming Note**

   The B value in register RB may be needed for invalidating ERAT entries corresponding to the translation being invalidated.

   **Programming Note**

   Use of `slbieg` to invalidate software-created segment descriptors is a programming error. The architecture requires that bolted entries not be invalidated by the instruction.
The information is for an SLB-derived translation and has a Class value of 1.
- The information is for a Radix Tree-derived translation for which effPID\ne0.

0b100
All SLB entries are invalidated. All implementation-specific lookaside information is invalidated.

0b110
All SLB entries except entry 0 are invalidated; SLB entry 0 is not invalidated. All implementation-specific lookaside information that satisfies any of the following conditions is invalidated:
- The information is for an SLB-derived or SLS translation.
- The information is for a Radix Tree-derived translation for which effLPID\ne0 or effPID\ne0.
- The information was created when address translation was disabled and MSR_{HV PR} was equal to 0b00.

0b111
No SLB entries are invalidated. All implementation-specific lookaside information is invalidated.

**Programming Note**

In the preceding description, “SLB-derived translation” excludes any SLS translation, since SLS translation does not use segmentation.

All other IH values are reserved. If the IH field contains a reserved value, the set of SLB entries and implementation-specific lookaside information that is invalidated by the instruction is undefined.

When IH=0b000, 0b100, or 0b111, execution of this instruction has the side effect of clearing the storage access history associated with the Hypervisor Real Mode Storage Control facility. See Section 6.7.3.2.1, “Hypervisor Real Mode Storage Control” for more details.

This instruction terminates any Segment Table walks being performed on behalf of the thread that executes it, and ensures that any new table walks will be performed using the current PIDR value.

This instruction is privileged.

**Special Registers Altered:**
None

**Programming Note**

When performing a context switch between processes, an HPT operating system will use \texttt{mtPIDR} followed by \texttt{slbia}. The synchronization of the PID value and termination of outstanding Segment Table walks ensures that SLB will not contain multiple entries mapping the same EA range (i.e. from the former and new PIDs). Note that if this sequence is performed with translation enabled, care must be taken to avoid an implicit branch. (i.e. the same translation(s) for the locations containing the context switch routine must be valid for both processes.)

For the corresponding situation when changing partitions from or to a partition using HPT translation, hypervisor software should get all the affected threads into real mode, execute \texttt{mtLPIDR}, and then perform the \texttt{slbia} on all the affected threads. (If the affected threads were not in real mode, avoiding implicit branches due to the \texttt{mtLPIDR} would be very difficult.)

**Programming Note**

\texttt{slbia} does not affect SLBs on other threads.

**Programming Note**

If \texttt{slbia} is executed when instruction address translation is enabled, software can ensure that attempting to fetch the instruction following the \texttt{slbia} does not cause an Instruction Segment interrupt by placing the \texttt{slbia} and the subsequent instruction in the effective segment mapped by SLB entry 0. (The preceding assumes that no other interrupts occur between executing the \texttt{slbia} and executing the subsequent instruction. It also assumes that IH values other than 0b011 and 0b100 are used.)
SLB Invalidate All Global  X-form

```
slbiag RS, L

0 31 RS  /// L  /// 850 /

- **RS\_53** \(K_P\)
- **RS\_54** N
- **RS\_55** L
- **RS\_56** C
- **RS\_57** must be 0b0
- **RS\_58:59** LP
- **RS\_60:63** must be 0b0000
- **RB\_0:35** ESID
- **RB\_36** V
- **RB\_37:51** must be 0b000 || 0x000
- **RB\_52:63** index, which selects the SLB entry

**Figure 49. GPR contents for slbmte**

On implementations that support a virtual address size of only \(n\) bits, \(n<78\), \((RS)_{2:79-n}\) must be zeros.

When LPCR\_UPRT=1, the value of index must not exceed 3. \((RB)_{52:61}\) are ignored.

High-order bits of \((RB)_{52:63}\) that correspond to SLB entries beyond the size of the SLB provided by the implementation must be zeros.

The hardware ignores the contents of RS and RB listed below and software must set them to 0s.

- **(RS)_{57}**
- **(RS)_{50:63}**
- **(RB)_{37:51}**

If this instruction is executed in 32-bit mode, \((RB)_{0:31}\) must be zeros (i.e., the ESID must be in the range 0:15).
This instruction must not be used to load a segment descriptor that is in the Segment Table when LPCR\textsubscript{UPRT}=1, and cannot be used to invalidate the translation contained in an SLB entry.

This instruction is privileged.

**Special Registers Altered:**

None

---

**Programming Note**

The reason `slbmte` must not be used to load segment descriptors that are in the Segment Table is that there could be a race condition with hardware loading the same segment descriptor, resulting in duplicate SLB entries. Software must not allow duplicate SLB entries to be created; see Section 6.7.8.2, “SLB Search”.

The reason `slbmte` cannot be used to invalidate an SLB entry is that it does not necessarily affect implementation-specific address translation lookaside information. `slbie` (or `slbia`) must be used for this purpose.

---

### SLB Move From Entry VSID X-form

<table>

**Figure 51. GPR contents for slbfee**

If the SLB entry specified by bits 52:63 of register RB is invalid (V=0), the contents of register RT are set to 0.

High-order bits of (RB)52:63 that correspond to SLB entries beyond the size of the SLB provided by the implementation must be zeros.

The hardware ignores the contents of RB0:51.

This instruction is privileged.

The use of the L field is implementation specific.

**Special Registers Altered:**

None

The SLB is searched for an entry that matches the effective address specified by register RB. When LPCR_UPRT=1, this instruction is nonfunctional. The search is performed as if it were being performed for purposes of address translation. That is, in order for a given entry to satisfy the search, the entry must be valid (V=1), and (RB)0:63-s must equal SLBE[ESID0:63-s] (where 2^s is the segment size selected by the B field in the entry). If exactly one matching entry is found, the contents of the B, VSID, Ks, Kp, N, L, C, and LP fields of the entry are placed into register RT. If no matching entry is found, register RT is set to 0. If more than one matching entry is found, either one of the matching entries is used, as if it were the only matching entry, or a Machine Check occurs. If a Machine Check occurs, register RT, and CR Field 0 are set to undefined values, and the description below of how this register and this field is set does not apply.

The contents of registers RT and RB are interpreted as shown in Figure 52.

**Figure 52. GPR contents for slbfee**

If s > 28, RT80-s:51 are set to zeros. On implementations that support a virtual address size of only n bits, n < 78, RT2:79-n are set to zeros.

CR Field 0 is set as follows. j is a 1-bit value that is equal to 0b1 if a matching entry was found. Otherwise, j is 0b0. When LPCR_UPRT=0, j=0b0.
**Programming Note**

When LPCR<sub>UPRT</sub>=0, the hypervisor can use `slbfee` to save the contents of any SLBE that the partition has created to map an ESID that is needed by an adjunct, and later use the saved contents to restore the partition-created SLBE after the adjunct has completed execution. The hypervisor must also use `slbie`, twice, first to invalidate the partition-created mapping and later to invalidate the adjunct's mapping.

When LPCR<sub>UPRT</sub>=1, the partition’s SLBE will be restored from the Segment Table by hardware, on demand, after the second `slbie` has been executed. There is no need for the hypervisor to save and restore the partition’s SLBE and hence no need to use `slbfee`.

When the need for LPCR<sub>UPRT</sub>=0 has ended, `slbfee` may be removed from the architecture. Programs that run with LPCR<sub>UPRT</sub>=1 should not use `slbfee`.

| CR0_LT_GTEQ_SO | = 0b00 || j || XER_SO |

---

<table>
<thead>
<tr>
<th>slbsync</th>
<th></th>
<th></th>
<th></th>
<th></th>
<th>31 31 31 31 31</th>
</tr>
</thead>
</table>

The `slbsync` instruction provides an ordering function for the effects of all `slbieg` and `slbiag` instructions executed by the thread executing the `slbsync` instruction, with respect to the memory barrier created by a subsequent `ptesync` instruction executed by the same thread. Executing a `slbsync` instruction ensures that all of the following will occur.

- All SLB invalidations caused by `slbieg` and `slbiag` instructions preceding the `slbsync` instruction will have completed on any other thread before any data accesses caused by instructions following the `ptesync` instruction are performed with respect to that thread.

- All storage accesses by other threads for which the address was translated using the translations being invalidated will have been performed with respect to the thread executing the `ptesync` instruction, to the extent required by the associated Memory Coherence Required attributes, before the `ptesync` instruction’s memory barrier is created.

The operation performed by this instruction is ordered by the `eieio` (or `[p]hwsync or `ptesync`) instruction with respect to preceding `slbieg` and `slbiag` instructions executed by the thread executing the `slbsync` instruction. The operations caused by `slbieg` or `slbiag` and `slbsync` are ordered by `eieio` as a fifth set of operations, which is independent of the other four sets that `eieio` orders.

The `slbsync` instruction may complete before operations caused by `slbieg` or `slbiag` instructions preceding the `slbsync` instruction have been performed.

This instruction is privileged except when LPCR<sub>GTSE</sub>=0, making it hypervisor privileged.

See Section 6.10 for a description of other requirements associated with the use of this instruction.

**Special Registers Altered:**

- None

---

| slbsync | should not be used to synchronize the completion of `slbie`. |
6.9.3.3 TLB Management Instructions

In addition to managing the TLB, `tlbie` and `tlbiel` are also used to manage the Page Walk Cache, In-Memory Table caching, and implementation-specific lookaside information that depends on the values of the PTEs. The parameters described below specify the type of translations to invalidate and the scope of the invalidation to be performed.

Radix Invalidation Control (RIC) specifies whether to invalidate the TLB, the Page Walk Cache, or both together with partition and Process Table caching. The RIC values and functions are as follows.

0 Just invalidate TLB.
1 Invalidate just Page Walk Cache.
2 Invalidate TLB, Page Walk Cache, and any caching of Partition and Process Table Entries.
3 Invalidate a group of translations (just in the TLB).

Process Scoped (PRS) specifies whether the translation(s) to be invalidated are partition scoped or process scoped including, for RIC=2, whether process or Partition Table caching is being invalidated.

0 Invalidate partition-scoped translation(s).
1 Invalidate process-scoped translations.

Radix (R) specifies whether the translations to be invalidated are Radix Tree translations or HPT translations. If the R value is incorrect for the target partition, the results of the operation are boundedly undefined. (R is ignored for invalidates with IS=3 and MSR_WV=1 because they have the potential to target translations for multiple partitions.)

0 Invalidate HPT translation(s).
1 Invalidate Radix Tree translations.

Invalidation Selector (IS) (found in RB) specifies the scope of the context to be invalidated.

0 Invalidate just the target VA.
1 Invalidate matching PID.
2 Invalidate matching LPID.
3 If MSR_WV=1, invalidate all entries, otherwise invalidate matching LPID.

The IS=0 RIC=2 variants of `tlbie` and `tlbiel` perform the same TLB invalidations as the corresponding RIC=0 variants, but in addition invalidate Page Walk Cache Entries and partition or Process Table caching associated with the specified LPID or LPID/PID. When RIC=1 and IS=0, the Page Walk Cache Entries for the specified LPID or LPID/PID are invalidated while leaving the corresponding TLB entries intact. The ability to target an individual Page Walk Cache Entry or the set of entries associated with a given Page Table Entry (i.e. IS=0 for RIC=1 or RIC=2) is not supported by the Power ISA. When RIC=3 and IS=0, `tlbie` invalidates a series of consecutive translations for HPT translation. For IS=0 invalidations of Radix Tree translations, the use of `tlbie[ ]` is limited to translations for quadrant 0.

When reassigning an LPID or PID, after updating the Partition and/or Process Table(s) software must use a `tlbie` instruction to remove lookaside information associated with the old partition or process.

To invalidate TLB entries, software must supply an effective page number for process-scoped Radix Tree translations, a guest real page number for partition-scoped Radix Tree translations, and an abbreviated virtual page number for HPT translations. The RTL, RB illustration, and verbal description for R=1 require the reader to make the appropriate mental substitution for partition-scoped invalidation. Note also that where page size is specified to be a function of L and AP, it may also be a function of L and LP. The architecture allows for three independent sets of page sizes, one for R=1, one for RIC=3 (requires R=0), and one for all other cases. An implementation may choose to have a single set of encodings work consistently between any two or all three states.

If this instruction is executed in hypervisor state,
RS32:63 contains the partition ID (LPID) of the partition
for which one or more translations are being invalid-
ated. Otherwise, the value in LPIDR is used. The
supported (RS)32:63 values are the same as the LPID
values supported in LPIDR. RS0:31 contains a PID
value. The supported values of RS0:31 are the same as
the PID values supported in PIDR.
The following forms are invalid.

- PRS=1, R=0, and RIC=2 (The only pro-
  cess-scoped HPT caching is of the Process Table.)
- RIC=1 and R=0 (There is no Page Walk Cache for
  HPT translation.)
- RIC=3 and R=1 (Group invalidation is only sup-
  ported for HPT translation.)
The following forms are treated as if the instruction
form were invalid.

- RIC=1 and IS=0 (The architecture does not sup-
  port shootout of individual translations in the
  Page Walk Cache.)
- RIC=2 and IS=0 (RIC is for comprehensive invali-
  dation that is not supported at the level of an indi-
  vidual page.)
- RIC=3 and IS=0 (Group invalidation is only sup-
  ported for individual pages.)
- PRS=0 and IS=1 (Partition-scoped translations
  are not associated with processes.)
- R=0, IS=1, and RIC=2 (HPT translations are not
  associated with processes.)
- R=0, RIC=2, PRS=0, HV=0, and IS=2 or 3 (The
  similar cases with RIC=0 allow the HPT OS to
  invalidate all of its TLB entries. The only incremen-
  tial function of these cases is to invalidate partition
table caching, which the OS is not permitted to do.)
The results of an attempt to invalidate a translation
outside of quadrant 0 for Radix Tree translation (R=1,
RIC=0, PRS=1, IS=0, and EA0:1≠0b00) are boundedly
undefined.

IS field in RB contains 0b00
If RIC=0, this is a search for a single TLB entry. The
following relationships must be true and tests and
actions are performed to search for an HPT translation.

If the base page size specified by the PTE that was
used to create the TLB entry to be invalidated is 4
KB, the L field in register RB must contain 0.

If the L field in RB contains 0, the base page size is
4 KB and RB56:58 (AP - Actual Page size field)
must be set to the SLBEI field encoding for the page
size corresponding to the actual page size speci-
fied by the PTE that was used to create the TLB
entry to be invalidated. Thus, b is equal to 12 and p
is equal to log2 (actual page size specified by
(RB)56:58). The Abbreviated Virtual Address (AVA)
field in register RB must contain bits 14:65 of the
virtual address translated by the TLB entry to be
invalidated. Variable i is equal to 51.

If the L field in RB contains 1, the following rules
apply.
The base page size and actual page size are
specified in the LP field in register RB, where
the relationship between (RB)34:51 (LP - Large
Page size selector field) and the base page
size and actual page size is the same as the
relationship between PTELP and the base
page size and actual page size (see Section 6.7.9.1 on page 1195 and Figure 33.
on page 1196). Thus, b is equal to \(\log_2\) (base page size specified by \((RB)_{44:51}\)) and \(p\) is equal to \(\log_2\) (actual page size specified by \((RB)_{44:51}\)). Specifically, \((RB)_{44+c:51}\) must be equal to the contents of bits \(c:7\) of the LP field of the PTE that was used to create the TLB entry to be invalidated, where \(c\) is the number of \("r"\) bits in the LP field of the PTE that was used to create the TLB entry to be invalidated.

Variable \(i\) is the larger of \((63-p)\) and the value that is the smaller of \(43\) and \((63-b)\). \((RB)_{0:i}\) must contain bits \(14:(i+14)\) of the virtual address translated by the TLB to be invalidated. If \(b>20\), \((RB)_{56:43}\) may contain any value and are ignored by the hardware.

If \(b<20\), \((RB)_{56:75-b}\) must contain bits \(58:77-b\) of the virtual address translated by the TLB to be invalidated, and other bits in \((RB)_{56:62}\) may contain any value and are ignored by the hardware.

If \(b\geq20\), \((RB)_{56:62}\) (AVAL - Abbreviated Virtual Address, Lower) may contain any value and are ignored by the hardware.

Let the segment size be equal to the segment size specified in \((RB)_{54:55}\) (B field). The contents of \((RB)_{54:55}\) must be the same as the contents of the B field of the PTE that was used to create the TLB entry to be invalidated.

\(RB_{52:53}\) and \(RB_{59:62}\) (when \((RB)_{63} = 0\)) must contain zeros and are ignored by the hardware.

All TLB entries on all threads that have all of the following properties are made invalid.

- The entry translates a virtual address for which any of the following conditions are met for the partition ID of the partition for which the translation is to be invalidated.
  - The IS field in RB contains 0b10 or MSR HV=0 and \(RIC=0\) or \(RIC=2\).
  - The IS field in RB contains 0b11, and TLBELPID matches the partition ID of the partition for which the translation is to be invalidated.

- The process ID specified in RS matches the process ID in the TLB entry if not invalidating a partition-scoped translation.
- TLBELPID matches the partition ID of the partition for which the translation is to be invalidated.

Additional TLB entries may also be made invalid if those TLB entries contain an LPID that matches the partition ID of the partition for which the translation is to be invalidated.

If \(RIC=3\), then the TLB entries mapping an aligned sequence of virtual pages are made invalid on all threads. The number of virtual pages in the sequence, and their page size (base page size = actual page size), are provided using an implementation-specific encoding of the GS field of RB. The number of virtual pages is a power of two. The abbreviated virtual address of the beginning of the sequence is provided by the AVA field of RB with the appropriate number of low-order bits treated as zero to cause the affected region of VA space to be aligned at a multiple of its size. The effect is as if a tlbie instruction with RIC=PRS=R=0 were executed for each virtual page in the sequence, using the supplied contents of RS and RB except using the AVA value corresponding to the virtual page and using the base and actual page size provided by GS.

**IS field in RB is non-zero**

If \(RIC=0\) or \(RIC=2\), all partition-scoped TLB entries when PRS=0 and either MSR HV=1 or R=0, or all process-scoped TLB entries when PRS=1 on all threads for which any of the following conditions are met for the entry are made invalid.

- The IS field in RB contains 0b10 or MSR HV=0 and the IS field contains 0b11, and TLBELPID matches the partition ID of the partition for which the translation is to be invalidated.
The IS field in RB contains 0b01, TLBE_LPID matches the partition ID of the partition for which the translation is to be invalidated, and TLBE_PPID=RS0:31.

- The IS field in RB contains 0b11 and MSR_HV=1.

If RIC=1 or RIC=2, if the following conditions are met, the respective partition-scoped contents when PRS=0 and MSR_HV=1 or process-scoped contents when PRS=1 of the page walk cache are invalidated.

- If the IS field in RB contains 0b10 or if IS contains 0b11 and MSR_HV=0, for all threads, all properly-scoped page walk caching associated with the partition for which the translation is to be invalidated is invalidated.

- If the IS field in RB contains 0b11 and MSR_HV=1, the entire properly-scoped page walk caching for each thread is invalidated.

- If the IS field in RB contains 0b01 (and PRS=1), for all threads, all properly-scoped page walk caching associated with process RS0:31 in the partition for which the translation is to be invalidated is invalidated.

If RIC=2, if the following conditions are met, the respective partition and Process Table caching are invalidated for all threads.

- If the IS field in RB contains 0b01 and PRS=1, for all threads, caching of Process Table Entries for process RS0:31 in the partition for which the translation is to be invalidated is invalidated.

- If the IS field in RB contains 0b10, MSR_HV=1, and PRS=0, for all threads, caching of Partition Tables for the partition for which the translation is to be invalidated is invalidated.

- If the IS field in RB contains 0b10 and PRS=1, for all threads, caching of Process Tables for the partition for which the translation is to be invalidated is invalidated.

- If the IS field in RB contains 0b11, MSR_HV=1, and PRS=0, for all threads, all Partition Table caching is invalidated.

- If the IS field in RB contains 0b11, MSR_HV=1, and PRS=1, for all threads, all Process Table caching is invalidated.

- If the IS field in RB contains 0b11, MSR_HV=0, and PRS=1, for all threads, caching of Process Tables for the partition for which the translation is to be invalidated is invalidated.

When i>40, RB40:i-1 may contain any value and are ignored by the hardware.

For all IS values

For all threads, any implementation specific lookaside information that is based on any TLB entry that would be invalidated by this instruction will also be invalidated.

MSR_SF must be 1 when this instruction is executed; otherwise the results are undefined.

If the value specified in RS0:31, RS32:63, RB54:55 when R=0, RB56:58 when RB63=0, or RB44:51 when RB63=1 is not supported by the implementation, the instruction is treated as if the instruction form were invalid.

The operation performed by this instruction is ordered by the `eieio` (or `phtlbe` or `ptsync`) instruction with respect to a subsequent `tlbsync` instruction executed by the thread executing the `tlbie` instruction. The operations caused by `tlbie` and `tlbsync` are ordered by `eieio` as a fourth set of operations, which is independent of the other four sets that `eieio` orders.

This instruction is privileged except when LPCR_GTSE=0 or when PRS=0 and HR=1, making it hypervisor privileged.

See Section 6.10, “Translation Table Update Synchronization Requirements” for a description of other requirements associated with the use of this instruction.

Special Registers Altered:

None

Extended Mnemonics:

Extended mnemonic for `tlbie`:

<table>
<thead>
<tr>
<th>Extended</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>tlbie</code> RB,RS</td>
<td><code>tlbie</code> RB,RS,0,0,0</td>
</tr>
</tbody>
</table>

Programming Note

`tlbie` serves as both a basic and an extended mnemonic. The Assembler will recognize a `tlbie` mnemonic with five operands as the basic form, and a `tlbie` mnemonic with two operands as the extended form. In the extended form the RIC, PRS, and R operands are omitted and assumed to be 0.

Programming Note

For `tlbie` instructions in which (RB)63=0, the AP value in RB is provided to make it easier for the hardware to locate address translations, in lookaside buffers, corresponding to the address translation being invalidated.

For `tlbie` instructions the AP specification is not binary compatible with versions of the architecture that precede Version 2.06. As an example, for an actual page size of 64 KB AP=0b101, whereas software written for an implementation that complies with a version of the architecture that precedes V. 2.06 would have AP=100 since AP was a 1 bit value followed by 0s in RB57:58. If binary compatibility is important, for a 64 KB page software can use AP=0b101 on these earlier implementations since these implementations were required to ignore RB57:58.
For \texttt{tlbie}[l] instructions the AVA and AVAL fields in RB contain different VA bits from those in PTEAVA.

An operating system that uses HPT translation should only use \texttt{tlbie} to invalidate the translation for a specific page when it knows whether VPM is active, and more specifically, what page size is actually in use for the target translation. The address comparison performed by \texttt{tlbie} is not sensitive to whether VPM is active. As a result, the operating system must supply an AVA value that is appropriate for the page size that is in use.

      associated with partition search_LPID

The operation performed by this instruction is based on
the contents of registers RS and RB. The contents of these registers are shown below, where IS is (RB)52:53
and L is (RB)63.

RS:

<table>
<thead>
<tr>
<th>PID</th>
<th>///</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>32</td>
</tr>
<tr>
<td>63</td>
<td></td>
</tr>
</tbody>
</table>

Programming Note

Note that although there is no PID compare for part-
tition-scoped translation, software must still place
the PID in RS when IS=0 or 1. It may be used, for example, in the TLB hash.

RB for R=1 and IS=0b00:

<table>
<thead>
<tr>
<th>EPN</th>
<th>IS</th>
<th>0s</th>
<th>AP</th>
<th>0s</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>52</td>
<td>54</td>
<td>56</td>
<td>59</td>
</tr>
</tbody>
</table>

RB for R=0, IS=0b00, and L=0:

<table>
<thead>
<tr>
<th>AVA</th>
<th>IS</th>
<th>B</th>
<th>AP</th>
<th>0s</th>
<th>L</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>52</td>
<td>54</td>
<td>56</td>
<td>59</td>
<td>63</td>
</tr>
</tbody>
</table>

Programming Note

In versions of the architecture that precede Version 3.1, \texttt{tlbiel} with IS= 1, 2, or 3 invalidated appropriate
entries only in a specific congruence class of the
TLB, specified by SET in register RB. As a result,
software was required to use a \texttt{tlbiel} loop to iterate
through all congruence classes in order to invali-
date the TLB. Software that will not be run on hard-
ware complying with those versions should specify
SET=0 in register RB. The description for \texttt{tlbiel}
specifies SET instead of 0 in register RB to illus-
trate compatibility with software written to run on
hardware complying with those versions.

LPIDR contains the partition ID (LPID) of the partition for
which the translation is being invalidated. RS0:31 con-
tains a PID value. The supported values of RS0:31 are
the same as the PID values supported in PIDR.

The following forms are invalid.

- PRS=1, R=0, and RIC≠2 (The only pro-
cess-scoped HPT caching is of the Process Table.)
- RIC=1 and R=0 (There is no Page Walk Cache for
  HPT translation.)
- RIC=3 (Group invalidation is not supported for
  \texttt{tlbiel}.)

The following forms are treated as though the instruc-
tion form was invalid.

- RIC=1 and IS=0 (The architecture does not sup-
  port shootdown of individual translations in the
  Page Walk Cache.)
- RIC=1 and SET≠0 (PWC invalidation never
  required a loop to iterate across congruence
  classes.)
- RIC=2 and IS=0 (RIC is for comprehensive invali-
dation that is not supported at the level of an indi-
  vidual page.)
- PRS=0 and IS=1 (Partition-scoped translations
  are not associated with processes.)
- R=0, IS=1, and RIC≠2 (HPT translations are not
  associated with processes.)
- R=0, RIC=2, PRS=0, HV=0, and IS=2 or 3 (The
  similar cases with RIC=0 allow the HPT OS to
  invalidate all of its TLB entries. The only incremen-
tal function of these cases is to invalidate partition
table caching, which the OS is not permitted to do.)
The results of an attempt to invalidate a translation outside of quadrant 0 for Radix Tree translation (R=1, RIC=0, PRS=1, IS=0, and EA0:i=0b00) are boundedly undefined.

**IS field in RB contains 0b00**

If RIC=0, this is a search for a single TLB entry. The following relationships must be true and tests and actions are performed to search for an HPT translation.

If the base page size specified by the PTE that was used to create the TLB entry to be invalidated is 4 KB, the L field in register RB must contain 0.

If the L field in RB contains 0, the base page size is 4 KB and RB56:58 (AP - Actual Page size field) must be set to the SLBE_LIP encoding for the page size corresponding to the actual page size specified by the PTE that was used to create the TLB entry to be invalidated. Thus, b is equal to 12 and p is equal to log2 (actual page size specified by RB56:58). The Abbreviated Virtual Address (AVA) field in register RB must contain bits 14:65 of the virtual address translated by the TLB entry to be invalidated. Variable i is equal to 51.

If the L field in RB contains 1, the following rules apply.

- The base page size and actual page size are specified in the LP field in register RB, where the relationship between (RB)44:51 (LP - Large Page size selector field) and the base page size and actual page size is the same as the relationship between PTE_LP and the base page size and actual page size (see Section 6.7.9.1 on page 1195 and Figure 33 on page 1196). Thus, b is equal to log2 (base page size specified by RB44:51) and p is equal to log2 (actual page size specified by RB44:51). Specifically, (RB)44+c:51 must be equal to the contents of bits c:7 of the LP field of the PTE that was used to create the TLB entry to be invalidated, where c is the number of “r” bits in the LP field of the PTE that was used to create the TLB entry to be invalidated.

- Variable i is the larger of (63-p) and the value that is the smaller of 43 and (63-b). (RB)0:i must contain bits 14:(i+14) of the virtual address translated by the TLB to be invalidated. If b>20, RB64:43 may contain any value and are ignored by the hardware.

- If b<20, (RB)56:75-b must contain bits 58:77-b of the virtual address translated by the TLB to be invalidated, and other bits in (RB)56:62 may contain any value and are ignored by the hardware.

- If b≥20, (RB)56:62 (AVAL - Abbreviated Virtual Address, Lower) may contain any value and are ignored by the hardware.

Let the segment size be equal to the segment size specified in (RB)56:55 (B field). The contents of RB56:55 must be the same as the contents of the B field of the PTE that was used to create the TLB entry to be invalidated.

All TLB entries that have all of the following properties are made invalid on the thread executing the `tlbiel` instruction.

- The entry translates a virtual address for which all the following are true.
  - VA14:14+i is equal to (RB)0:i.
  - L=0 or b≥20 or, if L=1 and b<20, VA56:77-b is equal to (RB)56:77-b.
  - The segment size of the entry is the same as the segment size specified in (RB)54:55.
  - Either of the following is true:
    - The L field in RB is 0, the base page size of the entry is 4 KB, and the actual page size of the entry matches the actual page size specified in (RB)56:58.
    - The L field in RB is 1, the base page size of the entry matches the base page size specified in (RB)44:51, and the actual page size of the entry matches the actual page size specified in (RB)44:51.
  - The entry is partition scoped.
  - TLBE_LPID = LPID_LPID.

The following relationships must be true and tests and actions are performed to search for a Radix Tree translation. For a partition-scoped invalidation, references to the effective address are understood to refer to the guest real address.

The page size is encoded in RB56:58 (AP - Actual Page size field). Thus p is equal to log2 (page size specified by RB56:58). The Effective Page Number (EPN) field in register RB must contain the bits 0:i of the effective address translated by the TLB entry to be invalidated. Variable i is equal to 63-p.

The fields shown as zeros must be set to zero and are ignored by the hardware.

All TLB entries that have all of the following properties are made invalid on the thread executing the `tlbiel` instruction...

- The entry translates an effective address for which EA0:i is equal to (RB)0:i.
- The page size of the entry matches the page size specified in (RB)56:58.
- The entry has the appropriate scope (partition or process).
- The process ID specified in RS matches the process ID in the TLB entry if not invalidating a partition-scoped translation.
- TLBE_LPID matches the partition ID of the partition for which the translation is to be invalidated.

**IS field in RB is non-zero**

When SET=0 is specified and either RIC=0 or RIC=2, each partition-scoped entry when PRS=0 and either MSR_HIV=1 or R=0, or each process-scoped entry when
PRS=1 is invalidated if any of the following conditions are met for the entry.
- The IS field in RB contains 0b10, or MSR$\text{HV}=0$ and the IS field contains 0b11, and TLBE$\text{LPID}=\text{LPID}_\text{LPI}$.  
- The IS field in RB contains 0b01, TLBE$\text{LPID}=\text{LPID}_\text{LPI}$, and TLBE$\text{PID}=\text{RS}_\text{R0:31}$.  
- The IS field in RB contains 0b11 and MSR$\text{HV}=1$.

When SET=0 is specified and either RIC=1 or RIC=2, if the following conditions are met, the respective partition-scoped contents when PRS=0 and MSR$\text{HV}=1$ or process-scoped contents when PRS=1 of the page walk cache are invalidated.
- If the IS field in RB contains 0b10 or if IS contains 0b11 and MSR$\text{HV}=0$, all properly-scoped page walk caching associated with partition LPDIR$\text{LPID}$ is invalidated.  
- If the IS field in RB contains 0b11 and MSR$\text{HV}=1$, the entire properly-scoped page walk caching is invalidated.  
- If the IS field in RB contains 0b01 (and PRS=1), all properly-scoped page walk caching associated with process $\text{RS}_\text{R0:31}$ in partition LPDIR$\text{LPID}$ is invalidated.

When SET=0 is specified and RIC=2, if the following conditions are met, the respective partition and Process Table caching are invalidated.
- If the IS field in RB contains 0b01 and PRS=1, caching of Process Table Entries for process $\text{RS}_\text{R0:31}$ in partition LPDIR$\text{LPID}$ is invalidated.  
- If the IS field in RB contains 0b10, MSR$\text{HV}=1$, and PRS=0, caching of Partition Tables for partition LPDIR$\text{LPID}$ is invalidated.  
- If the IS field in RB contains 0b10 and PRS=1, caching of Process Tables for partition LPDIR$\text{LPID}$ is invalidated.  
- If the IS field in RB contains 0b11, MSR$\text{HV}=1$, and PRS=0, all Partition Table caching is invalidated.  
- If the IS field in RB contains 0b11, MSR$\text{HV}=1$, and PRS=1, all Process Table caching is invalidated.  
- If the IS field in RB contains 0b11, MSR$\text{HV}=0$, and PRS=1, caching of Process Tables for partition LPDIR$\text{LPID}$ is invalidated.

For all IS values

Any implementation specific lookaside information that is based on any TLB entry that would be invalidated by this instruction will also be invalidated.

Depending on the variant of the instruction, RB$\text{R0:39}$, RB$\text{R59:62}$, RB$\text{R59:63}$, RB$\text{R54:55}$, and RB$\text{R54:63}$ are the equivalent of reserved fields, should contain 0s, and are ignored by the hardware.  RS$\text{R32:63}$ is always the equivalent of a reserved field, should contain 0s, and is ignored by the hardware.

Only TLB entries, page walk caching, and process and Segment Table caching on the thread executing the \text{tlb}i\text{e}l instruction are affected.

MSR$\text{SF}$ must be 1 when this instruction is executed; otherwise the results are boundedly undefined.

If the value specified in $\text{RS}_\text{R0:31}$, RB$\text{R54:55}$, RB$\text{R56:58}$, or RB$\text{R44:51}$, when it is needed to perform the specified operation, is not supported by the implementation, the instruction is treated as if the instruction form were invalid.

This instruction is privileged except when PRS=0 and HR=1, making it hypervisor privileged.

See Section 6.10, "Translation Table Update Synchronization Requirements" on page 1241 for a description of other requirements associated with the use of this instruction.

**Special Registers Altered:**
None

**Extended Mnemonics:**

Extended mnemonic for \text{tlb}i\text{e}l:

<table>
<thead>
<tr>
<th>Extended:</th>
<th>Equivalent to:</th>
</tr>
</thead>
<tbody>
<tr>
<td>\text{tlb}i\text{e}l \text{RB}</td>
<td>\text{tlb}i\text{e}l \text{RB},0,0,0,0</td>
</tr>
</tbody>
</table>

\text{tlb}i\text{e}l serves as both a basic and an extended mnemonic. The Assembler will recognize a \text{tlb}i\text{e}l mnemonic with five operands as the basic form, and a \text{tlb}i\text{e}l mnemonic with one operand as the extended form. In the extended form the RS, RIC, PRS, and R operands are omitted and assumed to be 0.

\text{tlb}i\text{e}l may be executed on a given thread even if the sequence \text{tlb}i\text{e}l - \text{eio} - \text{tlbsyc}n - \text{ptescyc} is concurrently being executed on another thread.

See also the Programming Notes with the description of the \text{tlb}i\text{e}l instruction.
The `tlbsync` instruction provides an ordering function for the effects of all `tlbiel` instructions executed by the thread executing the `tlbsync` instruction, with respect to the memory barrier created by a subsequent `ptesync` instruction executed by the same thread. Executing a `tlbsync` instruction ensures that all of the following will occur.

- All TLB invalidations caused by `tlbiel` instructions preceding the `tlbsync` instruction will have completed on any other thread before any data accesses caused by instructions following the `ptesync` instruction are performed with respect to that thread.

- All storage accesses by other threads for which the address was translated using the translations being invalidated, and all Reference and Change bit updates associated with address translations that were performed by other threads using the translations being invalidated, will have been performed with respect to the thread executing the `ptesync` instruction, to the extent required by the associated Memory Coherence Required attributes, before the `ptesync` instruction's memory barrier is created.

The operation performed by this instruction is ordered by the `eieio` (or `[p]hwsync or `ptesync`) instruction with respect to preceding `tlbiel` instructions executed by the thread executing the `tlbsync` instruction. The operations caused by `tlbiel` and `tlbsync` are ordered by `eieio` as a fourth set of operations, which is independent of the other three sets that `eieio` orders.

The `tlbsync` instruction may complete before operations caused by `tlbiel` instructions preceding the `tlbsync` instruction have been performed.

This instruction is privileged except when LPCRGTE=0, making it hypervisor privileged.

See Section 6.10 for a description of other requirements associated with the use of this instruction.

Special Registers Altered:

None

Programming Note

An operating system that uses HPT translation should only use `tlbiel` to invalidate the translation for a specific page when it knows whether VPM is active, and more specifically, what page size is actually in use for the target translation. The address comparison performed by `tlbiel` is not sensitive to whether VPM is active. As a result, the operating system must supply an AVA value that is appropriate for the page size that is in use.

```
| 31 | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 |  9 |  8 |  7 |  6 |  5 |  4 |  3 |  2 |  1 |  0 |
| b | b | 11 | 16 | 21 | 31 |
```

The `tlbsync` instruction should not be used to synchronize the completion of `tlbiel`.

**TLB Synchronize**

X-form

`tlbsync`

Programming Note

An operating system that uses HPT translation should only use `tlbiel` to invalidate the translation for a specific page when it knows whether VPM is active, and more specifically, what page size is actually in use for the target translation. The address comparison performed by `tlbiel` is not sensitive to whether VPM is active. As a result, the operating system must supply an AVA value that is appropriate for the page size that is in use.
This section describes rules that software must follow when updating the Translation Tables, and includes suggested sequences of operations for some representative cases. The sequences required for other cases may be deduced from the sequences that are provided and from this accompanying description.

In the sequences of operations shown in the following subsections, the Page Table Entry is assumed to be for a virtual page for which the base page size is equal to the actual page size. If these page sizes are different, multiple `tlbi` instructions are needed, one for each PTE corresponding to the virtual page.

In the sequences of operations shown in the following subsections, any alteration of a translation table entry that corresponds to a single line in the sequence is assumed to be done using a `Store` instruction for which the access is atomic. Appropriate modifications must be made to these sequences if this assumption is not satisfied (e.g., if a store doubleword operation is done using two `Store Word` instructions).

Two correctness-related considerations when choosing translation table update sequences are to be safe for multiple asynchronous sources of update (potentially both hardware and software), and to avoid paradoxes that in some cases could show up as multi-hits in the various translation caches. These considerations lead to the simple, contiguous sequences for general case updates that appear later in this section. Good performance is a third consideration that motivates deferring and/or batching invalidations or even omitting synchronization or invalidation from the general case. The viability of these techniques is determined by whether the lack of a single clear state across the system has problematic repercussions. The discussion of atomic Reference and Change bit updates alludes to one such example. (See Section 6.7.12.) Simpler optimizations are illustrated below.

The following are guidelines for safety when multiple sources of asynchronous updates are possible. To interact correctly with hardware that atomically updates Reference and Change bits (as well as with updates from other software threads), software should use atomic updates to modify valid PTEs. Academically speaking, if hardware uses simple loads and stores, software may either use locking and first invalidate the PTE and cached translations, or may attempt to optimize using atomic updates that don't change the values of the bytes containing the Reference and Change bits with the exception of potentially setting those specific bits to 1 or the Reference bit to 0. When modifying only bytes not subject to hardware modification, software may use either locking or atomic updates, subject to the limitations and optimizations described below. The realities of Reference and Change bit placement may severely limit what optimizations are possible when hardware uses normal loads and stores to update those bits.

To simplify verification and avoid paradoxes, non-impactful limitations are placed on translation table update sequence optimizations. One limitation is that software must not have two or more valid overlapping translations at any level of the translation process with different page or segment sizes. This means that one translation must be marked invalid in the translation table and invalidated from any caches prior to instating the second. The other limitation is that software must not have two or more valid translations with different attributes (i.e. WIMG, ATT). The example of I=1 and I=0 is obvious, but in general there is not enough to be gained to attempt to avoid invalidating one attribute setting before establishing another. In both of these cases, the translation cache invalidation may lag indefinitely behind the table entry invalidations and the cache invalidations may be batched, but must precede enabling the new attributes.

To protect software's ability to have reasonable performance, optimizations that hardware must support are also identified. (These optimizations are understood to be limited by the techniques used for hardware and software updates as described above, and by the properties of the table structure itself.) A convention for atomic updates will yield more opportunity than locking. Hardware that does not use atomic updates may limit or eliminate the opportunity for software to optimize. (The table structure for Radix Tree translation will yield more opportunity than the dual PTEG structure of HPT translation.) Access authority downgrades and setting Change bits to zero may be done without first marking the PTE invalid and invalidating the translation caches. The translation cache invalidation may lag the PTE change indefinitely and be done in bulk. Access authority upgrades and setting Reference and Change bits to 1 may be done without any PTE or translation cache invalidation. Software bits may be changed without any PTE or translation cache invalidation. Finally, any complete change to the RPN (non-overlapping with the original value) does not of itself require synchronization (though other changes to the PTE made at the same time might).

In the following examples, when the same type of sequence works for both types of translation, the HPT PTE is shown because it is more complex. In this description, and in references in subsequent subsections to "safe for multithreaded software," the safety is with respect to the risk of one thread overwriting another's update. There may also be concern for the creation of multiple matching translations, e.g. within a PTEG or pair of PTEGs. When the reservation granule is equal to or larger in size than the structure on which mutual exclusion must be ensured (e.g. PTE for Radix
Tree translation but PTEG for HPT translation), multiple entries will also be prevented. (Secondary hash groups will generally not be covered by the same reservation granule as primary hash groups.)

Updates (by software) to the tables are performed only when they are known to be required by the sequential execution model (see Section 6.5). Because address translation for instructions preceding a given Store instruction might cause an interrupt, and thereby prevent the corresponding store from being required by the sequential execution model, address translations for instructions preceding the Store instruction must be performed before the corresponding store is performed. As a result, an update to a translation table need not be preceded by a context synchronizing instruction.

All of the sequences require a context synchronizing operation after the sequence if the new contents of the translation table are to be used for address translations associated with subsequent instructions.

As noted in the description of the Synchronize instruction in Section 4.6.3 of Book II, address translation associated with instructions which occur in program order subsequent to the Synchronize (and this includes the ptesync variant) may be performed prior to the completion of the Synchronize. To ensure that these instructions and data which may have been speculatively fetched are discarded, a context synchronizing operation is required.

**Programming Note**

In many cases this context synchronization will occur naturally; for example, if the sequence is executed within an interrupt handler the rfid, rfscv, hrfid, or urfid instruction that returns from the interrupt handler may provide the required context synchronization.

Translation table entries must not be changed in a manner that causes an implicit branch.

### 6.10.1 Translation Table Updates

TLBs are non-coherent caches of the HTABs and Radix Trees. TLB entries must be invalidated explicitly with one of the TLB Invalidate instructions. SLBs are non-coherent caches of the Segment Tables, SLB entries must be invalidated explicitly with one of the SLB Invalidate instructions. Page Walk Caches are non-coherent caches of the intermediate steps in Radix Tree translation. Non-coherent caching of the Partition and Process Tables is permitted. Provision has been made for the use of the TLB Invalidate instructions to manage the types of caching described in the preceding two sentences at a PID or LPID granularity.

Unsynchronized lookups in the Page, Segment, and when HR=0, Process Tables continue even while they are being modified. (For Partition Table Entries, and for Process Table Entries when HR=1, the process or partition affected must be inactive because the entries do not have valid bits.) With the exceptions previously identified for Segment Table walks (see Section 6.9.3, “Lookaside Buffer Management”), any thread, including a thread on which software is modifying any of the set of tables described in the first sentence, may look in those tables at any time in an attempt to translate an address. When modifying an entry in any of the former set of tables, software must ensure that the table entry’s V bit is 0 if the table entry does not correctly specify its portion of the translation (e.g., if the RPN field is not correct for the current AVA field).

For HPT translation, updates of Reference and Change bits by the hardware are not synchronized with the accesses that cause the updates. When modifying doubleword 1 of a PTE, software must take care to avoid overwriting a hardware update of these bits and to avoid having the value written by a Store instruction overwritten by a hardware update.

The most basic sequence that will achieve proper system synchronization for PTE updates is the following.  
- tlbie instruction(s) specifying the same LPID operand
- slbsync or slbieg
- tlbie
- ptesync

Other instructions may be interleaved among these instructions. Operating system and hypervisor software that updates Page Table Entries should use this sequence.

Operating systems and nested hypervisors are exposed to being interrupted during this sequence. The interrupting hypervisor is responsible for completing the sequence above. In general this will require the hypervisor to include the following sequence in an interrupt handler.

- eieio
- tlbie
- ptesync

This sequence itself may be interrupted by a higher level hypervisor. When returning to the interrupted software, the original sequence will be completed. Hardware must tolerate the result of nested interleaving of these sequences. tlbie and tlbie sync instructions should only be used as part of these sequences.

The corresponding sequence for Segment Table updates uses slbieg in place of tlbie and slbsync in place of tlbie sync. Similarly slbieg and slbsync should only be used as part of these sequences. In circumstances where a hypervisor may be interrupting either a PTE update or a Segment Table update, it must include both tlbie sync and slbsync in its completing sequence, in either order. Hardware must tolerate the result of nested interleaving of these additional sequences.
The PTE sequence is also used to synchronize updates to Partition Table Entries, and to Process Table Entries that do not have valid bits. Mutual exclusion must be added if the update processes are multi-threaded.

On systems consisting of only a single-threaded processor, the eieio and tlbsync or slbsync instructions can be omitted.

The following subsections illustrate sequences that must be used for translation table updates to tables that are subject to concurrent use by hardware (i.e. that have valid bits in their entries). For Partition Table Entries and for Process Table Entries that do not have valid bits, simpler sequences consisting of just the preceding sequences, perhaps with mutual exclusion if the update processes are multithreaded, is sufficient.

--- Programming Note ---

The eieio instruction prevents the reordering of the preceding tlbie, slbibg, or slbibg instructions with respect to the subsequent tlbsync or slbsync instruction. The tlbsync or slbsync instruction and the subsequent ptesync instruction together ensure that all storage accesses for which the address was translated using the translations being invalidated (by the tlbie, slbibg, or slbibg instructions), and all Reference and Change bit updates associated with address translations that were performed using the translations being invalidated, will be performed with respect to any thread or mechanism, to the extent required by the associated Memory Coherence Required attributes, before any data accesses caused by instructions following the ptesync instruction are performed with respect to that thread or mechanism.

For Page Table update sequences that mark the PTE invalid (see Section 6.10.1.2, “Modifying a Translation Table Entry”), Reference and Change bit updates cease when the sequence is complete. When the PTE is marked invalid using an atomic update and the Store Conditional setting the entry invalid is successful, the Reference and Change bits obtained by the corresponding Load And Reserve instruction are stable/final values.

The sequences of operations shown in the following subsections assume a multi-threaded environment. In an environment consisting of only a single-threaded processor, the tlbsync or slbsync and the eieio that separates the tlbie or slbibg from the tlbsync or slbsync can be omitted. In a multi-threaded environment, when tlbie or slbibg is used instead of tlbie or slbibg in a Page or Segment Table update, the synchronization requirements are the same as when tlbie or slbibg is used in an environment consisting of only a single-threaded processor.

--- Programming Note ---

For all of the sequences shown in the following subsections, if it is necessary to communicate completion of the sequence to software running on another thread, the ptesync instruction at the end of the sequence should be followed by a Store instruction that stores a chosen value to some chosen storage location X. The memory barrier created by the ptesync instruction ensures that if a Load instruction executed by another thread returns the chosen value from location X, all subsequent searches of the Page or Segment Table by the other thread, that implicitly load from the PTE or STE specified by the sequence’s stores, will obtain the values stored (or values stored subsequently). The Load instruction that returns the chosen value should be followed by a context synchronizing instruction in order to ensure that all instructions following the context synchronizing instruction will be fetched and executed using the values stored by the sequence (or values stored subsequently). (These instructions may have been fetched or executed out-of-order using the old contents of the PTE or STE.)

This Note assumes that the Page or Segment Table and location X are in storage that is Memory Coherence Required.

6.10.1.1 Adding a Page Table Entry

This is the simplest Page Table case. The V bit of the old entry is assumed to be 0. The following sequence can be used to create a PTE, maintain a consistent state, and ensure that a subsequent reference to the virtual address translated by the new entry will use the correct real address and associated attributes. A single quadword store would avoid the need for the eieio. A similar sequence may be used to add a new Segment Table Entry. Mutual exclusion with respect to other software threads may be required, but there is no concern for interaction with hardware updates because the entry is invalid until the last store in the sequence.

```
PTE new values
pp  key  B  ARPN  LP  key  R  C  WING N  pp  key  B  ARPN
  // new values
pp   \* order 1st update before 2nd */
eieio  // order 1st update before 2nd */
PTEAVA SW L H V \* new values (V=1)
ptesync  \* order updates before next
Page Table search and before next
data access  */
```
PTE, maintain a consistent state (subject to the limitations described in the introduction to Section 6.10 such as avoiding overlapping translations), ensure that the translation instantiated by the old entry is no longer available, and ensure that a subsequent reference to the virtual address translated by the new entry will use the correct real address and associated attributes.

The following sequence is to interact correctly with atomic hardware updates. It returns stable Reference and Change bit values for the old translation and is safe for multiheaded software. If the purpose of the sequence is mainly to collect Reference and Change bit values for the old translation and is subject to non-atomic hardware updates, and is equivalent to deleting the STE and then adding a new one.) Mutual exclusion with respect to other software threads may be required. A similar sequence (except using tlbie with RIC=2 and tlbsync) may be used to modify HR=0 Process Table Entries.

General Case(STE)

If a valid entry is to be modified and the translation instantiated by the entry being modified is to be invalidated, the following sequence can be used to modify the STE, maintain a consistent state, ensure that the translation instantiated by the old entry is no longer available, and ensure that a subsequent reference to the effective address translated by the new entry will use the correct virtual address and associated attributes. (The sequence is much like the general case for a change to a PTE that is subject to non-atomic hardware updates, and is equivalent to deleting the STE and then adding a new one.) Mutual exclusion with respect to other software threads may be required. A similar sequence (except using tlbie with RIC=2 and tlbsync) may be used to modify HR=0 Process Table Entries.

Reseting the Reference Bit (PTE)

If the only change being made to a valid entry is to set the Reference bit to 0, a simpler sequence suffices because the Reference bit need not be maintained exactly. The byte store is exposed to overwriting another change being performed by multithreaded software, so mutual exclusion may be required.

Setting a Reference or Change Bit or Upgrading Access Authority (PTE Subject to Atomic Hardware Updates)

If the only change being made to a valid PTE that is subject to atomic hardware updates is to set the Refer-
ence or Change bit to 1 or to upgrade access authority, a simpler sequence suffices because the translation hardware will refetch the PTE if an access is attempted for which the only problems were reference and/or change bits needing to be set or insufficient access authority. The store is exposed to overwriting another change being performed by multithreaded software, so mutual exclusion may be required. (Note that changing EAA_0 can be both an upgrade and a downgrade, depending on the value of Key0 of the [[I]AMR]. If it is not solely an upgrade, the simpler sequence must not be used.)

PTE_V L SW R C ALT EAA ← new values (V=1)
ptesync /* order update before next Page Table search and before next data access */

Modifying the SW field (PTE)

If the only change being made to a valid entry is to modify the SW field, the following sequence suffices, because the SW field is not used by the hardware (i.e. is not cached in the TLB and has no effect on hardware behavior).

loop: ldarx r1 ← PTE_dwd_0 /* load dwd 0 of PTE */
if V=0 abort, else/*to interact with locking*/
rs157:60 ← new SW value /* replace SW, in r1 */
stdcx. PTE_dwd_0 ← r1 /* store dwd 0 of PTE */
if still reserved (new SW value, other fields unchanged) */
be- loop /* loop if lost reservation */

A ldarx/stdcx., lbarx/stbcx., or lwarx/stwcx. pair (specifying the low-order byte, halfword, or word respectively of doubleword 0 of the PTE) can be used instead of the ldarx/stdcx. pair shown above for HPT translation. The split SW field in the radix PTE cannot be updated with a single smaller atomic update. This sequence interacts correctly with hardware updates and is safe for multithreaded software. A similar sequence (including the possibility of using a smaller atomic update) can be used to update a Segment Table Entry.

Modifying the Effective Address (STE)

If the effective address translated by a valid STE is to be modified and the new effective address hashes to the same STEG as does the old effective address, the following sequence can be used to modify the STE, maintain a consistent state, ensure that the translation instantiated by the old entry is no longer available, and ensure that a subsequent reference to the effective address translated by the new entry will use the correct virtual address and associated attributes. Mutual exclusion with respect to other software threads may be required. The corresponding change of the virtual address in the PTE for HPT translation can be performed using a similar sequence, interacting correctly with non-atomic hardware table updates, as long as the second doubleword of the PTE is not stored.

STESID,V ← new values (V=1)
ptesync /* order update before slbieg and before next Segment Table search */
slbieg(old_B,old_ESID,old_TA,old_PID,old_LPID) /*invalidate old translation*/
eieio /* order slbieg before slbsync */
slbsync /* order slbieg before ptesync */
ptesync /* order slbieg, slbsync, and update before next data access */
Chapter 7. Interrupts

7.1 Overview

The Power ISA provides an interrupt mechanism to allow the thread to change state as a result of external signals, errors, or unusual conditions arising in the execution of instructions.

System Reset and Machine Check interrupts are not ordered. All other interrupts are ordered such that only one interrupt is reported, and when it is processed (taken) no program state is lost. Since Save/Restore Registers SRR0 and SRR1 are serially reusable resources used by most interrupts, program state may be lost when an unordered interrupt is taken.

7.2 Interrupt Registers

7.2.1 Machine Status Save/Restore Registers

When various interrupts occur, the state of the machine is saved in the Machine Status Save/Restore registers (SRR0 and SRR1). Section 7.5 describes which registers are altered by each interrupt.

SRR0

<table>
<thead>
<tr>
<th>Bit</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>62</td>
<td>63</td>
</tr>
</tbody>
</table>

SRR1

<table>
<thead>
<tr>
<th>Bit</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>62</td>
<td>63</td>
</tr>
</tbody>
</table>

Figure 53. Save/Restore Registers

SRR1 bits may be treated as reserved in a given implementation if they correspond to MSR bits that are reserved or are treated as reserved in that implementation and, for SRR1 bits in the range 33:36, 42:43, and 45:47, they are specified as being set either to 0 or to an undefined value for all interrupts that set SRR1 (including implementation-dependent setting, e.g. by the Machine Check interrupt or by implementation-specific interrupts). SRR144 cannot be treated as reserved, regardless of how it is set by interrupts, because it is used by software, as described in a Programming Note near the end of Section 7.5.9, “Program Interrupt” on page 1272.

7.2.2 Hypervisor Machine Status Save/Restore Registers

When various interrupts occur, the state of the machine is saved in the Hypervisor Machine Status Save/Restore registers (HSRR0 and HSRR1). Section 7.5 describes which registers are altered by each interrupt.

HSRR0

<table>
<thead>
<tr>
<th>Bit</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>62</td>
<td>63</td>
</tr>
</tbody>
</table>

HSRR1

<table>
<thead>
<tr>
<th>Bit</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>62</td>
<td>63</td>
</tr>
</tbody>
</table>

Figure 54. Hypervisor Save/Restore Registers

HSRR1 bits may be treated as reserved in a given implementation if they correspond to MSR bits that are reserved or are treated as reserved in that implementation and, for HSRR1 bits in the range 33:36 and 42:47, they are specified as being set either to 0 or to an undefined value for all interrupts that set HSRR1 (including implementation-dependent setting, e.g. by implementation-specific interrupts).

The HSRR0 and HSRR1 are hypervisor resources; see Chapter 2.

Programming Note

Execution of some instructions, and fetching instructions when MSR_{IR}=1 or MSR_{HV}=0, may have the side effect of modifying HSRR0 and HSRR1; see Section 7.4.4.

7.2.3 Ultravisor Machine Status Save/Restore Registers

When a Directed Ultravisor Doorbell interrupt occurs, the state of the machine is saved in the Ultravisor Machine Status Save/Restore Registers (USRR0 and USRR1).
USRR1 bits may be treated as reserved in a given implementation if they correspond to MSR bits that are reserved or are treated as reserved in that implementation and, for USRR1 bits in the range 33:36 and 42:47, they are specified as being set either to 0 or to an undefined value by the Directed Ultravisor Doorbell interrupt.

The USRR0 and USRR1 are ultravisor resources; see Chapter 3.

7.2.4 Access Segment Descriptor Register

The DAR, HDAR, SRR0, and HSRR0 generally provide the EA for storage exceptions. For hypervisor storage interrupts, additional information is often necessary to enable the hypervisor to handle the interrupt. This information is provided in a 64b SPR called the Access Segment Descriptor Register (ASDR). When nested Radix Tree translation is taking place, the ASDR will generally provide the guest real address down to bit 51. (The smallest supported page size is 4k.) When using paravirtualized HPT translation, information from the segment descriptor that was used to perform the effective to virtual translation is provided in the ASDR. For a big segment the values of the bits of the VSID field that are not part of the VSID are undefined. For exceptions that take place when translating the address of the process table entry or segment table entry group, only the VSID will be provided, because those addresses are specified as virtual addresses and the rest of the segment descriptor is implied. Some instances of the Machine Check interrupt may require the ASDR to be set similarly to how it is set for the hypervisor storage interrupts. The ASDR is set independent of the value of UPRT for the partition that is running.

7.2.5 Data Address Register

The Data Address Register (DAR) is a 64-bit register that is set by the Machine Check, Data Storage, Data Segment, and Alignment interrupts; see Sections 7.5.2, 7.5.3, 7.5.4, and 7.5.8. In general, when one of these interrupts occurs the DAR is set to an effective address associated with the storage access that caused the interrupt, with the high-order 32 bits of the DAR set to 0 if the interrupt occurs in 32-bit mode.

7.2.6 Hypervisor Data Address Register

The Hypervisor Data Address Register (HDAR) is a 64-bit register that is set by the Hypervisor Data Storage Interrupt; see Section 7.5.16. In general, when this interrupt occurs, the HDAR is set to an effective address associated with the storage access that caused the interrupt, with the high-order 32 bits of the HDAR set to 0 if the interrupt occurs in 32-bit mode.

7.2.7 Data Storage Interrupt Status Register

The Data Storage Interrupt Status Register (DSISR) is a 32-bit register that is set by the Machine Check, Data Storage, and Data Segment interrupts; see Sections 7.5.2, 7.5.3, and 7.5.4.
Figure 60. Data Storage Interrupt Status Register

DSISR bits may be treated as reserved in a given implementation if they are specified as being set either to 0 or to an undefined value for all interrupts that set the DSISR.

7.2.8 Hypervisor Data Storage Interrupt Status Register

The Hypervisor Data Storage Interrupt Status Register (HDSISR) is a 32-bit register that is set by the Hypervisor Data Storage interrupt. In general, when one of these interrupts occurs the HDSISR is set to indicate the cause of the interrupt.

Figure 61. Hypervisor Data Storage Interrupt Status Register

7.2.9 Hypervisor Emulation Instruction Register

The Hypervisor Emulation Instruction Register (HEIR) is a 64-bit register that is set by the Hypervisor Emulation Assistance interrupt; see Section 7.5.18. When a word instruction causes the interrupt, the image of the instruction that caused the interrupt is loaded into bits 32:63 of the register, and bits 0:31 are set to 0s. When a prefixed instruction causes the interrupt, the image of the instruction that caused the interrupt is loaded into bits 0:63 of the register.

There may be circumstances in which the suffix cannot be loaded, such as when the instruction is located in storage that is Caching Inhibited, or when the value of the suffix corresponds to a Branch instruction, rfebb, a context synchronizing instruction other than isync, or a “Service Processor Attention” instruction.

In such circumstances, bits 32:63 are set to 0s.

Figure 62. Hypervisor Emulation Instruction Register

<table>
<thead>
<tr>
<th>HEIR</th>
<th>32</th>
<th>63</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Programming Note

An access to the HMER is likely to be very slow. Software should access it sparingly.

7.2.10 Hypervisor Maintenance Exception Register

Each bit in the Hypervisor Maintenance Exception Register (HMER) is associated with one or more causes of the Hypervisor Maintenance exception, and is set when the associated exception(s) occur. If the corresponding bit in the Hypervisor Maintenance Exception Enable Register (HMEER) is set, a Hypervisor Maintenance Interrupt (HMI) may occur. If the thread is in a power-saving mode when the interrupt would have occurred, the thread will exit the power-saving mode; see Section 7.5.19 and Section 4.3.2.

Figure 63. Hypervisor Maintenance Exception Register

<table>
<thead>
<tr>
<th>HMER</th>
<th>32</th>
<th>63</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

| 0    | Set to 1 for a Malfunction Alert. |
| 1    | Set to 1 when performance is degraded for thermal reasons. |
| 2    | Set to 1 when thread recovery is invoked. |
| Others | Implementation-specific. |

When the mtspr instruction is executed with the HMER as the encoded Special Purpose Register, the contents of register RS are ANDed with the contents of the HMER and the result is placed into the HMER.

The exception bits in the HMER are sticky; that is, once set to 1 they remain set to 1 until they are set to 0 by an mthmer instruction.

Programming Note

When all prefixed instructions are made unavailable by the PCR setting, the prefix will be recognized as an illegal word instruction and placed in HEIR\textsubscript{32:63}.

7.2.11 Hypervisor Maintenance Exception Enable Register

The Hypervisor Maintenance Exception Enable Register (HMEER) is a 64-bit register in which each bit enables the corresponding exception in the HMER to cause the Hypervisor Maintenance interrupt, potentially causing exit from power-saving mode; see Section 7.5.19 and Section 4.3.2.

Figure 64. Hypervisor Maintenance Exception Enable Register

7.2.12 Facility Status and Control Register

The Facility Status and Control Register (FSCR) controls the availability of various facilities in problem state and indicates the cause of a Facility Unavailable interrupt.

When the FSCR makes a facility unavailable, attempted usage of the facility in problem state is treated as follows:

- Execution of an instruction causes a Facility Unavailable exception.
- Access of an SPR using mfspr/mtspr causes a Facility Unavailable exception.
- rfebb, rfid, rfscv, hrfid, urfid, and mtmsr[d] instructions have the same effect on bits in system registers as they would if the bits were available. The same is true for mtspr and mfspr unless the preceding item applies.

MMCR0 can also make various components of the Performance Monitor unavailable when accessed in problem state. An access to one of these components when it is unavailable causes a Facility Unavailable exception.

When the PCR makes a facility unavailable in problem state, the facility is treated as not defined in problem state; any Facility Unavailable interrupt that would occur if the facility were not made unavailable by the PCR does not occur.

When a Facility Unavailable interrupt occurs, the unavailable facility that was accessed is indicated in the most-significant byte of the FSCR.

</tr>
<tr>
<td>63</td>
<td></td>
</tr>
</tbody>
</table>

Figure 65. Facility Status and Control Register

The contents of the FSCR are specified below.

### Value Meaning

#### 0:7 Interruption Cause (IC)

When a Facility Unavailable interrupt occurs, the IC field contains a binary number indicating the facility for which access was attempted. The values and their meanings are specified below.

- 02 Access to the DSCR at SPR 3
- 03 Access to a Performance Monitor SPR in group A or B when MMCR0|PMCC is set to a value for which the access results in a Facility Unavailable interrupt. (See the definition of MMCR0|PMCC in Section 10.4.4.)
- 04 Execution of a BHRB Instruction
- 07 Access to an Event-Based Branch SPR or execution of an Event-Based Branch instruction
- 08 Access to the Target Address Register
- 0C Execution of scv
- 0D Execution of a prefixed instruction

All other values are reserved.

#### 8:63 Facility Enable (FE)

The FE field controls the availability of various facilities in problem state as specified below.

- Reserved
- 50 Prefixed Instruction
  - 0 Prefixed instructions are not available in problem state.
  - 1 Prefixed instructions are available in problem state unless made unavailable by another register.

- 51 scv instruction
  - 0 The scv instruction is not available.
  - 1 The scv instruction is available.

- 52:54 Reserved
- 55 Target Address Register (TAR)
  - 0 The TAR and bctar instruction are not available in problem state.
  - 1 The TAR and bctar instruction are available in problem state unless made unavailable by another register.

- 56 Event-Based Branch Facility (EBB)
  - 0 The Event-Based Branch facility SPRs and instructions are not available in problem state, and event-based exceptions and branches do not occur.
  - 1 The Event-Based Branch facility SPRs and instructions (see Chapter 6 of Book II) are available in problem state unless made unavailable by another register, and event-based exceptions and branches are allowed to occur if enabled by other registers.

- 57:60 Reserved

### Programming Note

HFSCRs<sub>59:60</sub> are used to control the availability of the Performance Monitor and the BHRB in problem and privileged non-hypervisor states. FSCRs<sub>59:60</sub> are reserved since the availability of the Performance Monitor and BHRB is controlled by MMCR0.

- 61 Data Stream Control Register at SPR 3 (DSCR)
  - 0 SPR 3 is not available in problem state.
Chapter 7. Interrupts

1 SPR 3 is available in problem state unless made unavailable by another register.

62:63 Reserved

--- Programming Note ---

When an OS has set the FSCR such that a facility is unavailable, the OS should either emulate the facility when it is accessed or provide an application interface that requires the application to request use of the facility before it accesses the facility.

7.2.13 Hypervisor Facility Status and Control Register

The Hypervisor Facility Status and Control Register (HFSCR) controls the availability of various facilities in problem and privileged non-hypervisor states, and indicates the cause of a Hypervisor Facility Unavailable interrupt.

When the HFSCR makes a facility unavailable, attempted usage of the facility in problem or privileged non-hypervisor states is treated as follows:

- Execution of an instruction causes a Hypervisor Facility Unavailable exception.
- Access of an SPR using mfspr/mtspr causes a Hypervisor Facility Unavailable exception
- rfebb, rfid, rfscv, hrfd, urfd, and mtmsr[d] instructions have the same effect on bits in system registers as they would if the bits were available. The same is true for mtspr and mfspr unless the preceding item applies.

When the PCR makes a facility unavailable in problem state, the facility is treated as not defined in problem state; any Hypervisor Facility Unavailable interrupt that would occur if the facility were not made unavailable by the PCR does not occur as a result of problem state access. See Section 2.5 for additional information.

When a Hypervisor Facility Unavailable interrupt occurs, the facility that was accessed is indicated in the most-significant byte of the HFSCR.

<table>
<thead>
<tr>
<th>IC</th>
<th>Facility Control</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:7</td>
<td>Interruption Cause (IC)</td>
</tr>
</tbody>
</table>

Figure 66. Hypervisor Facility Status and Control Register

The contents of the HFSCR are specified below.

Value Meaning

0:7 Interruption Cause (IC)

When a Hypervisor Facility Unavailable interrupt occurs, the IC field contains a binary number indicating the access that was attempted. The values and their meanings are specified below.

00 Access to a Floating Point register or execution of a Floating Point instruction
01 Access to a Vector or VSX register or execution of a Vector or VSX instruction
02 Access to the DSCR at SPRs 3 or 17
03 Read or write access of a Performance Monitor SPR in group A, or read access of a Performance Monitor SPR in group B. (See Section 10.4.1 for a definition of groups A and B.)
04 Execution of a BHRB Instruction
07 Access to an Event-Based Branch SPR or execution of an Event-Based Branch instruction
08 Access to the Target Address Register
09 Access to the stop instruction in privileged non-hypervisor state when one or more of the following conditions exist.
PSSCR_EC=1
PSSCR_ESL=1
PSSCR_MTL>PSSCR_PSLL
PSSCR_RL>PSSCR_PSLL
0A Access to the msgsndp or msgclrp instructions, the TIR or the DPDES Register

All other values are reserved.

--- Programming Note ---

There is no bit in this register controlling the availability of the stop instruction because the availability of stop in privileged non-hypervisor state is controlled by the PSSCR. See Section 4.2.2.

msgsndp instructions and SPRs (MSGP)

0 The msgsndp and msgclrp instructions and the TIR and DPDES registers are not available in privileged non-hypervisor state.
1 The msgsndp and msgclrp instructions and the TIR and DPDES registers are available in privileged non-hypervisor state unless made unavailable by another register.

53 Reserved

Chapter 7. Interrupts     1251
### Target Address Register (TAR)

0 The TAR and `bctar` instruction are not available in problem and privileged non-hypervisor state.

1 The TAR and `bctar` instruction are available in problem and privileged states unless made unavailable by another register.

### Event-Based Branch Facility (EBB)

0 The Event-Based Branch facility SPRs and instructions are not available in problem and privileged non-hypervisor states, and event-based exceptions and branches do not occur.

1 The Event-Based Branch facility SPRs and instructions are available in problem and privileged states unless made unavailable by another register, and event-based exceptions and branches are allowed to occur if enabled by other bits.

### Data Stream Control Register (DSCR)

0 SPR 3 is not available in problem or privileged non-hypervisor states and SPR 17 is not available in privileged non-hypervisor state.

1 SPR 3 is available in problem and privileged states and SPR 17 is available in privileged state unless made unavailable by another register.

### Vector and VSX Facilities (VECVSX)

0 The facilities whose availability is controlled by either MSRVEC or MSRVEX are not available in problem and privileged non-hypervisor states.

1 The facilities whose availability is controlled by either MSRVEC or MSRVEX are available in problem and privileged states unless made unavailable by another register.

### Floating Point Facility (FP)

0 The facilities whose availability is controlled by MSRFP are not available in problem and privileged non-hypervisor states.

1 The facilities whose availability is controlled by MSRFP are available in problem and privileged states unless made unavailable by another register.

---

### Programming Note

The FSCR can be used to determine whether a particular facility is being used by an application, and the HFSCR can be used to determine whether a particular facility is being used by either an application or by an operating system. This is done by disabling the facility initially, and enabling it in the interrupt handler upon first usage. The information about the usage of a particular facility can be used to determine whether that facility’s state must be saved and restored when changing program context.
Programming Note

The following tables summarize the interrupts that occur as a result of accessing the non-privileged Performance Monitor registers in problem state when MMCR0<sub>PMCC</sub>, PCR, and HFSCR are set to various values. (Accesses to privileged Performance Monitor SPRs (SPRs 784-792, 795-798) in problem state result in Privileged Instruction Type Program interrupts.)

<td>HU&lt;sup&gt;4&lt;/sup&gt;</td>
</tr>
</tbody>
</table>

Notes:
1. Terminology:
   - FU: Facility Unavailable interrupt
   - HE: Hypervisor Emulation Assistance interrupt
   - HU: Hypervisor Facility Unavailable interrupt
2. This SPR is read-only, and cannot be written in any privilege state. (See the mtosp instruction description in Section 5.4.4 for additional information.) FU or HU interrupts do not occur regardless of the value of MMCR0<sub>PMCC</sub> or HFSCR<sub>PM</sub>.
3. When the PCR indicates a version of the architecture prior to V 2.07, this SPR is treated as undefined in problem state; no FU or HU interrupts occur regardless of the value of MMCR0<sub>PMCC</sub> or HFSCR<sub>PM</sub>.
4. An HU interrupt occurs if HFSCR<sub>PM</sub>=0 when this SPR is accessed in either problem state or privileged non-hypervisor state.
5. An FU interrupt occurs only if PCR indicates a version of the architecture subsequent to V 3.0 and MMCR0<sub>PMCC</sub>EXT is set.
6. When the PCR indicates a version of the architecture prior to V 3.1, this SPR is treated as undefined in problem state; no FU or HU interrupts occur regardless of the value of MMCR0<sub>PMCC</sub> or HFSCR<sub>PM</sub>.
When an MSR bit makes a facility unavailable, the facility is made unavailable in all privilege states. Examples of this include the Floating Point, Vector, and VSX facilities. The FSCR and HFSCR affect the availability of facilities only in privilege states that are lower than the privilege of the register (FSCR or HFSCR).
7.3 Interrupt Synchronization

When an interrupt occurs, SRR0, HSRR0, or USRR0 is set to point to an instruction such that all preceding instructions have completed execution, no subsequent instruction has begun execution, and the instruction addressed by SRR0, HSRR0, or USRR0 may or may not have completed execution, depending on the interrupt type.

With the exception of System Reset and Machine Check interrupts, all interrupts are context synchronizing as defined in Section 1.5.1. System Reset and Machine Check interrupts are context synchronizing if they are recoverable (i.e., if bit 62 of SRR1 is set to 1 by the interrupt). If a System Reset or Machine Check interrupt is not recoverable (i.e., if bit 62 of SRR1 is set to 0 by the interrupt), it acts like a context synchronizing operation with respect to subsequent instructions. That is, a non-recoverable System Reset or Machine Check interrupt need not satisfy items 1 through 3 of Section 1.5.1, but does satisfy items 4 and 5.

7.4 Interrupt Classes

Interrupts are classified by whether they are directly caused by the execution of an instruction or are caused by some other system exception. Those that are “system-caused” are:

- System Reset
- Machine Check
- External
- Decrementer
- Directed Privileged Doorbell
- Hypervisor Decrementer
- Hypervisor Maintenance
- Hypervisor Virtualization
- Directed Hypervisor Doorbell
- Directed Ultravisor Doorbell
- Performance Monitor

External, Decrementer, Hypervisor Decrementer, Directed Privileged Doorbell, Directed Hypervisor Doorbell, Directed Ultravisor Doorbell, Hypervisor Maintenance, and Hypervisor Virtualization interrupts are maskable interrupts. Therefore, software may delay the generation of these interrupts. System Reset and Machine Check interrupts are not maskable.

“Instruction-caused” interrupts are further divided into two classes, precise and imprecise.

7.4.1 Precise Interrupt

Except for the Imprecise Mode Floating-Point Enabled Exception type Program interrupt, all instruction-caused interrupts are precise.

When the fetching or execution of an instruction causes a precise interrupt, the following conditions exist at the interrupt point:

1. SRR0, HSRR0, and USRR0 addresses either the instruction causing the exception or the immediately following instruction. Which instruction is addressed can be determined from the interrupt type and status bits.

2. An interrupt is generated such that all instructions preceding the instruction causing the exception appear to have completed with respect to the executing thread.

3. The instruction causing the exception may appear not to have begun execution (except for causing the exception), may have been partially executed, or may have completed, depending on the interrupt type.

4. Architecturally, no subsequent instruction has begun execution.

7.4.2 Imprecise Interrupt

This architecture defines one imprecise interrupt, the Imprecise Mode Floating-Point Enabled Exception type Program interrupt.

When an Imprecise Mode Floating-Point Enabled Exception type Program interrupt occurs, the following conditions exist at the interrupt point:

1. SRR0 addresses either the instruction causing the exception or some instruction following that instruction; see Section 7.5.9, “Program Interrupt” on page 1272.

2. An interrupt is generated such that all instructions preceding the instruction addressed by SRR0 appear to have completed with respect to the executing thread.

3. The instruction addressed by SRR0 may appear not to have begun execution (except, in some cases, for causing the interrupt to occur), may have been partially executed, or may have completed; see Section 7.5.9.

4. No instruction following the instruction addressed by SRR0 appears to have begun execution.

All Floating-Point Enabled Exception type Program interrupts are maskable using the MSR bits FE0 and FE1. Although these interrupts are maskable, they differ significantly from the other maskable interrupts in that the masking of these interrupts is usually controlled by the application program, whereas the masking of all other maskable interrupts is controlled by either the operating system or the hypervisor.
7.4.3 Interrupt Processing

Associated with each kind of interrupt is an interrupt vector, which contains the initial sequence of instructions that is executed when the corresponding interrupt occurs.

Interrupt processing consists of saving a small part of the thread’s state in certain registers, identifying the cause of the interrupt in other registers, and continuing execution at the corresponding interrupt vector location. When an exception exists that will cause an interrupt to be generated and it has been determined that the interrupt will occur, the following actions are performed. The handling of Machine Check interrupts (see Section 7.5.2) and System Call Vectored interrupts (see Section 7.5.27) differs from the description given below in several respects.

1. SRR0, HSRR0, or USRR0 is loaded with an instruction address that depends on the type of interrupt; see the specific interrupt description for details.
2. Bits 33:36 and 42:47 of SRR1, HSRR1, or USRR1 are loaded with information specific to the interrupt type.
3. Bits 0:32, 37:41, and 48:63 of SRR1, HSRR1, or USRR1 are loaded with a copy of the corresponding bits of the MSR.
4. The MSR is set as shown in Figure 67 on page 1261. In particular, MSR bits IR and DR are set as specified by LPCRAIL or LPCRHAIL as appropriate (see Section 2.2), and MSR bit SF is set to 1, selecting 64-bit mode. The new values take effect beginning with the first instruction executed following the interrupt.
5. Instruction fetch and execution resumes, using the new MSR value, at the effective address specific to the interrupt type. These effective addresses are shown in Figure 68 on page 1262. An offset may be applied to get the effective addresses, as specified by LPCRAIL or LPCRHAIL as appropriate (see Section 2.2).

Interrupts do not clear reservations obtained with lbarx, lharx, lwaxr, ldaxr, or lqarx.

---

Programming Note

In general, when an interrupt occurs, the following instructions should be executed by the interrupt handler before dispatching a “new” program on the thread.

- stbcx, sthcx, stwcx, stdcx, or stqcx, to clear the reservation if one is outstanding, to ensure that a lbarx, lharx, lwaxr, ldaxr, or lqarx in the interrupted program is not paired with a stbcx, sthcx, stwcx, stdcx, stqcx, or waitrsy on the “new” program.
- “eieio, tlbsync, slbsync, ptesync,” to complete any outstanding translation table modification sequence and ensure that all storage accesses caused by the interrupted program will be performed with respect to another thread before the program is resumed on that other thread. (If software conventions are such that there is no possibility of a translation table modification sequence being in progress on the thread, a [p]hwsync instruction suffices.)
- isync or rfid, to ensure that the instructions in the “new” program execute in the “new” context.
- cpabort, to clear state from any previous use of the Copy-Paste Facility.
For instruction-caused interrupts, in some cases it may be desirable for the operating system to emulate the instruction that caused the interrupt, while in other cases it may be desirable for the operating system not to emulate the instruction. The following list, while not complete, illustrates criteria by which decisions regarding emulation should be made. The list applies to general execution environments; it does not necessarily apply to special environments such as program debugging, bring-up, etc.

In general, the instruction should be emulated if:

- The interrupt is caused by a condition for which the instruction description (including related material such as the introduction to the section describing the instruction) implies that the instruction works correctly. Example: Alignment interrupt caused by `lmw` for which the storage operand is not aligned, or by `dcbz` for which the storage operand is in storage that is Write Through Required or Caching Inhibited.

- The instruction is an illegal instruction that should appear, to the program executing it, as if it were supported by the implementation. Example: A Hypervisor Emulation Assistance interrupt is caused by an instruction that has been phased out of the architecture but is still used by some programs that the operating system supports.

If the instruction is a Storage Access instruction, the emulation must satisfy the atomicity requirements described in Section 1.4 of Book II.

In general, the instruction should not be emulated if:

- The purpose of the instruction is to cause an interrupt. Example: System Call interrupt caused by `sc`.

- The interrupt is caused by a condition that is stated, in the instruction description, potentially to cause the interrupt. Example: Alignment interrupt caused by `lwarx` for which the storage operand is not aligned.

- The program is attempting to perform a function that it should not be permitted to perform. Example: Data Storage interrupt caused by `lwz` for which the storage operand is in storage that the program should not be permitted to access. (If the function is one that the program should be permitted to perform, the conditions that caused the interrupt should be corrected and the program re-dispatched such that the instruction will be re-executed. Example: Data Storage interrupt caused by `lwz` for which the storage operand is in storage that the program should be permitted to access but for which there currently is no PTE that satisfies the Page Table search.)
7.4.4 Implicit alteration of HSRR0 and HSRR1

Executing some of the more complex instructions may have the side effect of altering the contents of HSRR0 and HSRR1. The instructions listed below are guaranteed not to have this side effect. Any omission of instruction suffixes is significant; e.g., add is listed but add. is excluded.

1. **Branch instructions**
   - \( b[l][a], \) bc\( [l][a], \) bc\( tr[l], \) bc\( ctr[l] \)

2. **Fixed-Point Load and Store Instructions**
   - \( lbz, \) lb\( zx \), \( lhz, \) lh\( zx \), \( lwz, \) lw\( zx \), \( ld, \) ld\( x \), \( std, \) st\( bx \), st\( h, \) st\( hx \), st\( w, \) st\( wx \), st\( d, \) st\( dx \)

Execution of these instructions is guaranteed not to have the side effect of altering HSRR0 and HSRR1 only if the storage operand is aligned and MSR\( _{HV DR} = 0b100. \)

3. **Arithmetic instructions**
   - addi, addis, add, subf, neg

4. **Compare instructions**
5. **Logical and Extend Sign instructions**

    - `ori, oris, xori, xoris, and, or, xor, nand, nor, eqv, andc, orc, extsb, extsh, extsw`

6. **Rotate and Shift instructions**

    - `rldicl, rldicr, rldic, rlwinm, rlcl, rlm, rldimi, rlwimi, sld, slw, srd, srw`

7. **Other instructions**

    - `isync`
    - `rfid, urfid`
    - `hrfid` in hypervisor state
    - `mtspr, mfspr, mtmsrd, mfmsr`

**Programming Note**

Instructions excluded from the list include the following:

- Instructions that set or use XERCA
- Instructions that set XEROV or XERSO
- `andi, andis`, and fixed-point instructions with Rc=1 (Fixed-point instructions with Rc=1 can be replaced by the corresponding instruction with Rc=0 followed by a Compare instruction.)
- All floating-point instructions
- `mftb`

These instructions, and the other excluded instructions, may be implemented with the assistance of the Hypervisor Emulation Assistance interrupt, or of implementation-specific interrupts that modify HSRR0 and HSRR1. The included instructions are guaranteed not to be implemented thus. (The included instructions are sufficiently simple as to be unlikely to need such assistance. Moreover, they are likely to be needed in interrupt handlers before HSRR0 and HSRR1 have been saved or after HSRR0 and HSRR1 have been restored.)

Similarly, fetching instructions may have the side effect of altering the contents of HSRR0 and HSRR1 unless MSR_{HV IR} = 0b10.
7.5 Interrupt Definitions

Figure 67 shows all the types of interrupts and the values assigned to the MSR for each. Figure 68 shows the effective address of the interrupt vector for each interrupt type. (Section 6.7.5 on page 1184 summarizes all architecturally defined uses of effective addresses, including those implied by Figure 68.)

*Settings for Other Bits*

Bits PR and PMM are set to 0.

The TE field is set to 0b00.

FP, VEC, VSX, and bits 5 and 31 are set to 0.

If the interrupt results in MSR_SHV being equal to 0b11, the LE bit is copied from the UIL_E bit; otherwise, if the interrupt results in MSR_SHV being equal to 0b01, the LE bit is copied from the HILE bit; otherwise the LE bit is copied from the LPCRILE bit.

The SF bit is set to 1.

Reserved bits are set as if written as 0.
7.5.1 System Reset Interrupt

If a System Reset exception causes an interrupt that is not context synchronizing or causes the loss of a Machine Check exception or a Direct External exception, or if the state of the thread has been corrupted, the interrupt is not recoverable.

When the thread is in any power-saving level, a System Reset interrupt occurs when a System Reset exception exists. When the thread is in a power-saving level that was entered when PSSCREC=1, a System Reset interrupt also occurs when any of the following events occurs provided that the event is enabled to cause exit from power-saving mode (see Section 2.2). When the thread is in a power-saving level that allows the state of the LPCR to be lost, it is implementation-specific whether the following events, when enabled, cause exit, or whether only a system-reset exception causes exit.

- **External**
Decrementer
Directed Privileged Doorbell
Directed Hypervisor Doorbell
Directed Ultravisor Doorbell
Hypervisor Maintenance
Hypervisor Virtualization exception
Implementation-specific

SRR1 indicates the exception that caused exit from power-saving mode as specified below.

The following registers are set:

**SRR0**
If the interrupt did not occur when the thread was in power-saving mode, set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present; if the interrupt occurred when the thread was in a power-saving mode that was entered with PSSCR bit ESL=0, and fields RL, MTL, and PSLL set to values that do not allow state loss, set to the effective address of the instruction following the stop instruction; otherwise, set to an undefined value.

If the interrupt occurred while the thread was in power-saving mode, set to the effective address of the instruction following the **stop** instruction when **stop** is executed with PSSCR bit ESL=0 and fields RL, MTL, and PSLL set to values that do not allow state loss; otherwise, set to an undefined value.

--- Programming Note ---

Whenever **stop** is executed in privileged non-hypervisor state, the hypervisor typically sets both PSSCRESL and PSSCREC to 0, and sets RL and MTL to values that do not cause state loss. If an interrupt causes exit to power-saving mode (either because the interrupt was a System Reset or Machine Check interrupt or MSREE=1), then SRR0 for that interrupt contains the effective address of the instruction immediately following **stop**.

**SRR1**

**33** Implementation-dependent.

**34:36** Set to 0.

**42:45** If the interrupt did not occur when the thread was in power-saving mode, set to an implementation-specific value. If the interrupt occurred when the thread was in power-saving mode, set to indicate the exception that caused exit from power-saving mode as shown below:

<table>

**46:47** Set to indicate whether the interrupt occurred when the thread was in power-saving mode and, if so, the extent to which resource state was maintained while the thread was in power-saving mode, as follows:

| 00 | The interrupt did not occur when the thread was in power-saving mode. |
| 01 | The interrupt occurred when the thread was in power-saving mode. The state of all resources was maintained as if the thread was not in power-saving mode. |
The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, but the state of all hypervisor resources, including the DEC, HDEC, TB, PURR, SPURR, and VTB, was maintained as if the thread was not in power-saving mode and the state of all other resources is such that the hypervisor can resume execution. (See Section 2.6 for the list of hypervisor resources.)

The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, and the state of some hypervisor resources was not maintained or the state of some resources is such that the hypervisor cannot resume execution.

Programming Note

Although the resources that are maintained in power-saving levels that allow loss of state are implementation-dependent, the hypervisor can avoid implementation-dependence in the portion of the System Reset and Machine Check interrupt handlers that recover from having been in power-saving mode by using the contents of SRR1_{46:47}, to determine what state to restore. To avoid implementation-dependence, the hypervisor must assume that only the resources indicated in SRR1_{46:47} have been preserved.

The interrupt occurred when the thread was in power-saving mode. If the interrupt did not occur while the thread was in a power-saving level that was entered when PSSCR_{EC}=1, loaded from bit 62 of the MSR if the thread is in a recoverable state; otherwise set to 0. If the interrupt occurred while the thread was in a power-saving level that was entered when PSSCR_{EC}=1, set to 1 if the thread is in a recoverable state; otherwise set to 0.

Others

Loaded from the MSR.

MSR

See Figure 67 on page 1261.

In addition, if the interrupt occurs when the thread is in a power-saving level that was entered when PSSCR_{EC}=1 and is caused by an exception other than a System Reset exception, all other registers, except HSRR0 and HSRR1, that would be set by the corresponding interrupt if the exception occurred when the thread was not in power-saving mode are set by the System Reset interrupt, and are set to the values to which they would be set if the exception occurred when the thread was not in power-saving mode.

Execution resumes at effective address 0x0000_0000_0000_0100.

The means for software to distinguish between power-on Reset and other types of System Reset are implementation-dependent.

7.5.2 Machine Check Interrupt

The causes of Machine Check interrupts are implementation-dependent. For example, a Machine Check interrupt may be caused by a reference to a storage location that contains an uncorrectable error or does not exist (see Section 6.6), or by an error in the storage subsystem. In some cases, processor designers may choose to present what would normally be considered a storage exception, and reported as an [H]DSI or [H]ISI, as a Machine Check interrupt instead, often because of the perceived severity of the programming error or the difficulty of the verification and testing associated with reporting the error as an [H]DSI or [H]ISI. If the decision to report the exception as a Machine Check interrupt is made when the scenario is first added to the architecture, the exception may never be documented in a storage interrupt description. One such case is an attempt to access storage mapped to an accelerator as anything other than an operand of copy or paste.

When the thread is not in power-saving mode, Machine Check interrupts are enabled when MSR_{ME}=1; if MSR_{ME}=0 and a Machine Check exception occurs, the thread enters the Checkstop state. When the thread is in a power-saving level that does not allow loss of hypervisor state, Machine Check interrupts are treated as enabled when LPCR_{S1}=1 and cannot occur when LPCR_{S1}=0. When the thread is in a power-saving level that allows loss of hypervisor state, it is implementation-specific whether Machine Check interrupts are treated as enabled LPCR_{S1}=1 or if they cannot occur. If a Machine Check exception occurs while the thread is in power-saving mode and the Machine Check exception is not enabled to cause exit from power-saving mode, the result is implementation specific.

The Checkstop state may also be entered if an access is attempted to a storage location that does not exist (see Section 6.6), or if an implementation-dependent hardware error occurs that prevents continued operation.

Disabled Machine Check (Checkstop State)

When a thread is in Checkstop state, instruction processing is suspended and generally cannot be restarted without resetting the thread. Some implementations may preserve some or all of the internal state of
the thread when entering Checkstop state, so that the state can be analyzed as an aid in problem determination.

**Enabled Machine Check**

If a Machine Check exception causes an interrupt that is not context synchronizing or causes the loss of a Direct External exception, or if the state of the thread has been corrupted, the interrupt is not recoverable.

The following registers are set:

**SRR0**

- If the interrupt occurred when the thread was not in a power-saving mode, or was in a power-saving mode that was entered with PSSCR bit ESL=0, and fields RL, MTL, and PSLL set to values that do not allow state loss, set on a "best effort" basis to the effective address of some instruction that was executing or was about to be executed when the Machine Check exception occurred; otherwise set to an undefined value.

**SRR1**

- If SRR0 is set to the effective address of an instruction for which the instruction length can easily be reported, set to 0 if the instruction is a word instruction and to 1 if the instruction is a prefixed instruction; otherwise set to an undefined value.

**46:47**

- Set to indicate whether the interrupt occurred when the thread was in power-saving mode and, if so, the extent to which resource state was maintained while the thread was in power-saving mode, as follows.

  - **00** The interrupt did not occur when the thread was in power-saving mode.
  - **01** The interrupt occurred when the thread was in power-saving mode. The state of all resources was maintained as if the thread was not in power-saving mode.
  - **10** The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, but the state of all hypervisor resources, including the DEC, HDEC, TB, PURR, SPURR, and VTB, was maintained as if the thread was not in power-saving mode and the state of all other resources is such that the hypervisor can resume execution. (See Section 2.6 for the list of hypervisor resources.)
  - **11** The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, and the state of some hypervisor resources was not maintained or the state of some resources is such that the hypervisor cannot resume execution.

**Programming Note**

Although the resources that are maintained in power-saving mode (except when all resources are maintained) are implementation-dependent, the hypervisor can avoid implementation-dependence in the portion of the System Reset and Machine Check interrupt handlers that recover from having been in power-saving mode by using the contents of SRR146:47 to determine what state to restore. (To avoid implementation-dependence in the portion of the hypervisor that enters power-saving mode, the hypervisor must use the specification of the four instructions to determine what state to save.)

**Others**

- Set to an implementation-dependent value.

**MSR**

- See Figure 67.

**DSISR**

- Set to an implementation-dependent value.

**DAR**

- Set to an implementation-dependent value.

**ASDR**

- Set to an implementation-dependent value.
Execution resumes at effective address 0x0000_0000_0000_0200.

A Machine Check interrupt caused by the existence of multiple SLB entries or TLB entries (or similar entries in implementation-specific translation caches) which translate a given effective or virtual address (see Sections 6.7.8.2 and 6.7.9.2.) must occur while still in the context of the partition that caused it. The interrupt must be presented in a way that permits continuing execution, with damage limited to the causing partition. Treating the exception as instruction-caused will achieve these requirements.

---

**Programming Note**

If a Machine Check interrupt is caused by an error in the storage subsystem, the storage subsystem may return incorrect data, which may be placed into registers. This corruption of register contents may occur even if the interrupt is recoverable.

---

### 7.5.3 Data Storage Interrupt (DSI)

A Data Storage interrupt occurs when no higher priority exception exists and either

(a) (MSRHV PR=0b10) & (MSRDR=0)) and the data access cannot be performed, or

(b) HPT translation is being performed, the value of the expression

\[
(\text{MSR}_{HV} \text{ PR}=0b10) \land (\neg \text{VPM}) \land \text{PRTE}_{V} \land \text{MSR}_{DR}=1
\]

is 1, and a data access cannot be performed, except for the case of MSR$_{HV}$PR=0b10, VPM=0, LPCR$_{KBV}=1$, and a Virtual Page Class Key Storage Protection exception exists or

(c) Radix Tree translation is being performed, and either a Data Address Watchpoint match occurs, an attempt is made to execute an AMO with an invalid function code, an attempt is made to perform a copy-paste transfer other than from main storage to a properly initiated accelerator, a problem other than page fault or unsupported MMU configuration caused by (RTS or RPDS in) the PATE occurs attempting to access the LPID=0 process table, or process-scoped translation prevents the data access from being performed

for any of the following reasons that can occur in the respective translation state except for a PTEG access causing a Secure Memory Protection exception when VPM=0:

- Data address translation is enabled (MSR$_{DR}=1$) and the effective or virtual address of any byte of the storage location specified by a Load, Store, icbi, dbz, dcbs, or dcdf instruction cannot be translated to a real address because no valid PTE was found for the process-scoped Radix Tree translation or HPT translation with VPM off.
- The address of the appropriate process table entry or segment table entry group cannot be translated when HR=0 and either VPM=0 or the process table entry is invalid (independent of VPM).
- The effective address specified by a lq, lq, lwat, lbarx, lbarx, lbarx, lwat, lbart, sbcx, stbcx, stbcx, stwcx, stbcx, or stqcx instruction refers to storage that is Write Through Required or Caching Inhibited; or the effective address specified by a copy or paste instruction refers to storage that is Caching Inhibited; or the effective address specified by a lwat, ldat, stwat, or stdat instruction refers to storage that is Guarded.
- An accelerator is specified as the source of a copy instruction or an attempt is made to access an accelerator that is not properly configured for the software’s use.
- The access violates Basic Storage Protection.
- The access violates Virtual Page Class Key Storage Protection and LPCR$_{KBV}=0$.
- The access violates Radix Tree Storage Protection because the process-scoped PTE does not permit the access.
- The access violates Secure Memory Protection.
- The process- and partition-scoped page attributes conflict.
- An unsupported radix tree configuration is found for the process-scoped tables, or, if effLPID=0, for the partition-scoped tables. (Note that this condition may not be detected until the associated values are about to cause a functional problem for the processor.)
- A reference or change bit update cannot be performed in a process-scoped PTE.
- A Data Address Watchpoint match occurs.
- An attempt is made to execute a Load Atomic or Store Atomic instruction with an invalid function code.
- An attempt is made to execute a Fixed-Point Load or Store Caching Inhibited instruction with MSR$_{DR}=1$ or specifying a storage location that is specified by the Hypervisor Real Mode Storage Control facility to be treated as non-Guarded.

A Data Storage interrupt also occurs when no higher priority exception exists and an attempt is made to execute a Load Atomic or Store Atomic instruction specifying an invalid function code.

---

**Programming Note**

When an attempt to execute a Load Atomic or Store Atomic instruction containing an invalid function code (see Figures 3 and 4 in Book II) causes a DSI, the condition is very similar to an invalid form of an instruction. As a result, this instance of DSI occurs with a high priority that blocks the translation process and prevents Reference and Change bit updates.
If a *stbcx*, *sthcx*, *stwcx*, or *stdcx*, would not perform its store in the absence of a Data Storage interrupt, and either (a) the specified effective address refers to storage that is Write Through Required or Caching Inhibited, or (b) a non-conditional Store to the specified effective address would cause a Data Storage interrupt, it is implementation-dependent whether a Data Storage interrupt occurs.

If the XER specifies a length of zero for an indexed Move Assist instruction, a Data Storage interrupt does not occur.

The following registers are set:

- **SRR0**: Set to the effective address of the instruction that caused the interrupt.
- **SRR1**:  
  - 33: Set to 0.  
  - 34: Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.  
  - 35:36: Set to 0.  
  - 42:47: Set to 0.  
  - Others: Loaded from the MSR.
- **MSR**: See Figure 67.
- **DSISR**:  
  - 32: Set to 0.  
  - 33: Set to 1 if MSRDR=1 and the translation for an attempted access is not found in the Page Table; otherwise set to 0.  
  - 34: Set to 1 if the process- and partition-scoped page attributes conflict; otherwise set to 0.  
  - 35: Set to 0.  
  - 36: Set to 1 if the access is not permitted by Figure 45 or the privilege, read, or read/write bits in Figure 46 as appropriate; otherwise set to 0.  
  - 37: Set to 1 if the access is due to a *lq*, *stq*, *lqat*, *ldat*, *lbarx*, *lqax*, *stdat*, *stdcx*, *stdat*, or *stqcx*. instruction that addresses storage that is Write Through Required or Caching Inhibited; or if the access is due to a *copy* or *paste*. instruction that addresses storage that is Caching Inhibited; or if the access is due to a *lqat*, *ldat*, *stqat*, *stqcx*, *stdat*, or *stdat*. instruction that addresses storage that is Guarded; otherwise set to 0.  
  - 38: Set to 1 for a *Store*, *dcbz*, or *Load/Store Atomic* instruction; otherwise set to 0.  
  - 39:40: Set to 0.  
  - 41: Set to 1 if a Data Address Watchpoint match occurs; otherwise set to 0.  
  - 42: Set to 1 if the access is not permitted by virtual page class key protection; otherwise set to 0.  
  - 43: Set to 1 if the access is not permitted by Secure Memory Protection; otherwise set to 0.  
  - 44: Set to 1 if an unsupported radix tree configuration is found during the translation process; otherwise set to 0.  
  - 45: Set to 1 if an attempt to atomically set a reference or change bit fails; otherwise set to 0.

### Programming Note

The number of attempts hardware makes to atomically set reference and change bits before triggering this exception is implementation dependent. The POWER9 processor makes no attempt. Software may still support the atomic update programming model to get performance benefits such as those described in Section 6.7.12.

- **46**: Set to 1 if the address of the appropriate process table entry or segment table entry group cannot be translated when VPM=0 and HR=0, or the process table entry is invalid (independent of VPM) when HR=0.
- **47:59**: Set to 0.
- **60**: Set to 1 if an accelerator is specified as the source of a *copy* instruction or an attempt is made to access an accelerator that is not properly configured for the software’s use; otherwise set to 0. These exceptions are presented differently from most instruction-caused exceptions. See Section 4.4, “Copy-Paste Facility”, in Book II for details. Additional information may be retained by the platform if the accelerator is not properly configured.
- **61**: Set to 1 if an attempt is made to execute a *Load Atomic* or *Store Atomic* instruction specifying an invalid function code; otherwise set to 0.
- **62**: Set to 1 if an attempt is made to execute a *Fixed-Point Load* or *Store Caching Inhibited* instruction with MSRDR=1 or specifying a storage location that is specified by the Hypervisor Real Mode Storage Control facility to be treated as non-Guarded.
- **63**: Set to 0.
- **64**: Set to the effective address of a storage element as described in the following list. The list should be read from the top down; the DAR is set as described by the first item that corresponds to an exception that is reported in the DSISR. For example, if a *Load Word* instruction causes a storage protection violation and a Data Address Watchpoint match (and both are reported in the DSISR), the DAR is set to the effective address of the instruction that caused the interrupt.

---

**Chapter 7. Interrupts**  1267

[Revision Information]
address of a byte in the first aligned double-word for which access was attempted in the page that caused the exception.
- undefined, for Load Atomic or Store Atomic instruction specifying an invalid function code
- undefined, when DSISRb0=1
- a Data Storage exception occurs for reasons other than a Data Address Watchpoint match
  - a byte in the block that caused the exception, for a Cache Management instruction
  - a byte in the first aligned double-word for which access was attempted in the page that caused the exception, for a Load or Store instruction ("first" refers to address order: see Section 7.7).
- the first byte of overlap between the operand and the matching watched range, for a Data Address Watchpoint match

For the cases in which the DAR is specified above to be set to a defined value, if the interrupt occurs in 32-bit mode the high-order 32 bits of the DAR are set to 0.

If multiple Data Storage exceptions occur for a given effective address, any one or more of the bits corresponding to these exceptions may be set to 1 in the DSISR. However, if one or more Data Storage exceptions occur together with a Virtualized Page Class Key Storage Protection exception that occurs when LPCRKBV=1 and Virtualized Partition Memory is disabled by VPM=0, an HDSI results, and all of the exceptions are reported in the HDSISR.

Execution resumes at effective address 0x0000_0000_0000_0300, possibly offset as specified in Figure 68.

### 7.5.4 Data Segment Interrupt

For Paravirtualized HPT Translation, a Data Segment interrupt occurs when no higher priority exception exists and a data access cannot be performed because data address translation is enabled and the effective address of any byte of the storage location specified by a Load, Store, icbi, dcbz, dcbs, or dcbf instruction cannot be translated to a virtual address because the SLB search fails and, if UPRT=1, the Segment Table search fails after the STEG has been accessed.

For Radix Tree Translation, a Data Segment interrupt occurs when no higher priority exception exists and a data access cannot be performed because for the effective address specified by a Load, Store, icbi, dcbz, dcbs, or dcbf instruction, data address translation is enabled and either EA0:1=0b01 or 0b10 when MSRHV PR ≠ 0b10 or EA0:1=0b00 when MSRHV PR=0b10 and LPIDR≠0, or EA2:63 is outside the range translated by the appropriate Radix Tree.

If a stb.cx, stbcx, stwcx, stdcx, or stqcx. would not perform its store in the absence of a Data Segment interrupt and a non-conditional Store to the specified effective address would cause a Data Segment interrupt, it is implementation-dependent whether a Data Segment interrupt occurs.

If the XER specifies a length of zero for an indexed Move Assist instruction, a Data Segment interrupt does not occur.

The following registers are set:

| SRR0 | Set to the effective address of the instruction that caused the interrupt. |
| SRR1 | 33  | Set to 0. |
|      | 34  | Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction. |
|      | 35:36 | Set to 0. |
|      | 42:47 | Set to 0. |
| Others | Loaded from the MSR. |

| MSR | See Figure 67. |
| DAR | Set to undefined value. |

The following registers are set:

| SRR0 | Set to the effective address of a storage element as described in the following list. |
| SRR1 | 33  | Set to 0. |
|      | 34  | Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction. |
|      | 35:36 | Set to 0. |
|      | 42:47 | Set to 0. |
| Others | Loaded from the MSR. |

A Data Segment interrupt occurs if MSRDR=1 and the translation of the effective address of any byte of the specified storage location is not found in the SLB (or in any implementation-specific address translation lookaside information).

---

**Programming Note**

A Data Segment interrupt occurs if MSRDR=1 and the translation of the effective address of any byte of the specified storage location is not found in the SLB (or in any implementation-specific address translation lookaside information).
7.5.5 Instruction Storage Interrupt (ISI)

An Instruction Storage interrupt occurs when no higher priority exception exists and either
(a) \((\text{MSR}_{\text{HVPR}}=0b10) \& (\text{MSR}_{\text{IR}}=0))\) and the next instruction to be executed cannot be fetched, or
(b) HPT Translation is being performed, the value of the expression
\(((\text{MSR}_{\text{HVPR}}=0b10) \lor ((\neg \text{VPM}) \lor \neg \text{PRTEV}) \& \text{MSR}_{\text{IR}}))\) is 1, and the next instruction to be executed cannot be fetched, or
(c) Radix Tree translation is being performed and either a problem other than page fault or unsupported MMU configuration caused by (RTS or RPDS in) the PATE occurs attempting to access the LPID=0 process table or process-scoped translation prevents the next instruction to be executed from being fetched

for any of the following reasons that can occur in the respective translation state except for a PTEG access causing a Secure Memory Protection exception when VPM=0.

- Instruction address translation is enabled and the effective or virtual address cannot be translated to a real address because no valid PTE was found for the process-scoped Radix Tree translation or HPT translation with VPM off.
- The address of the appropriate process table entry or segment table entry group cannot be translated when HR=0 and either VPM=0 or the process table entry is invalid (independent of VPM).
- The access violates Basic Storage Protection.
- The access violates Virtual Page Class Key Storage Protection.
- The access violates Radix Tree Translation Storage Protection.
- The access violates Secure Memory Protection.
- The process- and partition-scoped page attributes conflict.
- An unsupported radix tree configuration is found for the process-scoped tables, or, if effLPID=0, for the partition-scoped tables. (Note that this condition may not be detected until the associated values are about to cause a functional problem for the processor.)
- A reference bit update cannot be performed in a process-scoped PTE.
- The instruction is a prefixed instruction and is in storage that is Caching Inhibited.

The following registers are set:

<table>
<thead>
<tr>
<th>SRR0</th>
<th>Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present (if the interrupt occurs on attempting to fetch a branch target, SRR0 is set to the branch target address).</th>
</tr>
</thead>
<tbody>
<tr>
<td>SRR1</td>
<td>Set to 1 if MSR_{IR}=1 and the translation for an attempted access is not found in the Page Table; otherwise set to 0.</td>
</tr>
<tr>
<td>33</td>
<td>Set to 1 if the process- and partition-scoped page attributes conflict; otherwise set to 0.</td>
</tr>
<tr>
<td>34</td>
<td>Set to 1 if the access is to No-execute (as indicated by the N bit in the segment table entry or the N bit in the HPT PTE or the Execute and Privilege bits in the EAA field of the Radix PTE and IAMR key 0) or Guarded storage, or is to Caching Inhibited storage and is for a prefixed instruction; otherwise set to 0.</td>
</tr>
<tr>
<td>35</td>
<td>Set to 1 if the access is not permitted by Figure 45 or the privilege or execute bits in Figure 46 as appropriate; otherwise set to 0.</td>
</tr>
<tr>
<td>36</td>
<td>Set to 1 if the access is not permitted by virtual page class key protection; otherwise set to 0.</td>
</tr>
<tr>
<td>42</td>
<td>Set to 1 if the access is not permitted by Secure Memory Protection; otherwise set to 0.</td>
</tr>
<tr>
<td>43</td>
<td>Set to 1 if an unsupported radix tree configuration is found during the translation process; otherwise set to 0.</td>
</tr>
<tr>
<td>44</td>
<td>Set to 1 if an attempt to atomically set a reference bit fails; otherwise set to 0.</td>
</tr>
<tr>
<td>45</td>
<td>Set to 1 if the address of the appropriate process table entry or segment table entry group cannot be translated when VPM=0 and HR=0, or the process table entry is invalid (independent of VPM) when HR=0.</td>
</tr>
<tr>
<td>46</td>
<td>Set to 1 if the address of the appropriate process table entry or segment table entry group cannot be translated when VPM=0 and HR=0, or the process table entry is invalid (independent of VPM) when HR=0.</td>
</tr>
<tr>
<td>47</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>Others</td>
<td>Loaded from the MSR.</td>
</tr>
<tr>
<td>MSR</td>
<td>See Figure 67.</td>
</tr>
</tbody>
</table>

Programming Note

The number of attempts hardware makes to atomically set reference and change bits before triggering this exception is implementation dependent. The POWER9 processor makes no attempt. Software may still support the atomic update programming model to get performance benefits such as those described in Section 6.7.12.

46 Set to 1 if the address of the appropriate process table entry or segment table entry group cannot be translated when VPM=0 and HR=0, or the process table entry is invalid (independent of VPM) when HR=0.

47 Set to 0.

Others Loaded from the MSR.

MSR See Figure 67.

If multiple Instruction Storage exceptions occur due to attempting to fetch a single instruction, any one or more of the bits corresponding to these exceptions may be set to 1 in SRR1.

Execution resumes at effective address 0x0000_0000_0000_0400, possibly offset as specified in Figure 68.
7.5.6 Instruction Segment Interrupt

For Paravirtualized HPT Translation, an Instruction Segment interrupt occurs when no higher priority exception exists and the next instruction to be executed cannot be fetched because instruction address translation is enabled and the effective address cannot be translated to a virtual address because the SLB search fails and, if UPRT=1, the Segment Table search fails after the STEG has been accessed.

For Radix Tree Translation, an Instruction Segment interrupt occurs when no higher priority exception exists and the next instruction to be executed cannot be fetched because instruction address translation is enabled and either $EA_{0:1}=0b01$ or $0b10$ when $MSR_{HVPR} \neq 0b10$ or $EA_{0:1}=0b00$ when $MSR_{HVPR}=0b10$ and $LPIDR=0$, or $EA_{2:63}$ is outside the range translated by the appropriate Radix Tree.

The following registers are set:

**SRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present (if the interrupt occurs on attempting to fetch a branch target, SRR0 is set to the branch target address).

**SRR1**
- $33:36$ Set to 0.
- $42:47$ Set to 0.
- Others Loaded from the MSR.

**MSR** See Figure 67 on page 1261.

Execution resumes at effective address $0x0000_0000_0000_0480$, possibly offset as specified in Figure 68.

---

**Programming Note**

An Instruction Segment interrupt occurs if $MSR_{SR}=1$ and the translation of the effective address of the next instruction to be executed is not found in the SLB (or in any implementation-specific address translation lookaside information).

7.5.7 External Interrupt

An External interrupt is classified as being either a Direct External interrupt or a Mediated External interrupt. Throughout this Book, usage of the phrase 'External interrupt', without further classification, refers to both a Direct External interrupt and a Mediated External interrupt.

7.5.7.1 Direct External Interrupt

A Direct External interrupt occurs when no higher priority exception exists, a Direct External exception exists, and the value of the expression

$$MSR_{EE} \land \neg (MSR_{HV} \land \neg MSR_{PR} \land LPCR_{HEIC}) \lor \neg (LPES) \lor (\neg MSR_{HV} \lor MSR_{PR})$$

is one. The occurrence of the interrupt does not cause the exception to cease to exist.

---

**Programming Note**

When HEIC=1, Direct External exceptions will not result in external interrupts when the processor is in hypervisor state even if $MSR_{EE}=1$. This enables the Hypervisor Virtualization interrupt handler to prevent External interrupts from occurring during the Hypervisor Virtualization interrupt handler.

When LPES=0, the following registers are set:

**HSRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**HSRR1**
- $33:36$ Set to 0.
- $42:47$ Set to 0.
- Others Loaded from the MSR.

**MSR** See Figure 67 on page 1261.

When LPES=1, the following registers are set:

**SRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**SRR1**
- $33:36$ Set to 0.
- $42:47$ Set to 0.
- Others Loaded from the MSR.

**MSR** See Figure 67 on page 1261.

Execution resumes at effective address $0x0000_0000_0000_0500$, possibly offset as specified in Figure 68.

---

**Programming Note**

Because the value of $MSR_{EE}$ is always 1 when the thread is in problem state, the simpler expression

$$MSR_{EE} \land \neg (MSR_{HV} \land \neg MSR_{PR} \land LPCR_{HEIC}) \lor \neg (LPES) \lor (\neg MSR_{HV} \lor MSR_{PR})$$

is equivalent to the expression given above.
Programming Note

The Direct External exception has the same meaning as the External exception in versions of the architecture prior to Version 2.05.

7.5.7.2 Mediated External Interrupt

A Mediated External interrupt occurs when no higher priority exception exists, a Mediated External exception exists (see the definition of LPCRMER in Section 2.2), and the value of the expression

\[ \text{MSR}_{EE} \& (\neg(\text{MSR}_{HV}) \mid \text{MSR}_{PR}) \]

is one. The occurrence of the interrupt does not cause the exception to cease to exist.

When LPES=0, the following registers are set:

- **HSRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **HSRR1**:
  - 0x33:36 Set to 0.
  - 0x42 Set to 1.
  - 0x43:47 Set to 0.
- **Others**: Set to 0.
- **MSR**: See Figure 67 on page 1261.

When LPES=1, the following registers are set:

- **SRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **SRR1**: 
  - 0x33:36 Set to 0.
  - 0x42 Set to 1.
  - 0x43:47 Set to 0.
- **Others**: Loaded from the MSR.
- **MSR**: See Figure 67 on page 1261.

Execution resumes at effective address 0x0000_0000_0000_0500, possibly offset as specified in Figure 68.

7.5.8 Alignment Interrupt

Most causes of Alignment interrupt involve storage operands, and many of those causes involve the alignment thereof. Storage operand alignment is defined in Section 1.10.1 of Book I. Another cause of Alignment interrupt is attempt to execute a prefixed instruction that crosses a 64-byte address boundary.

An Alignment interrupt occurs when no higher priority exception exists and an attempt is made to execute an instruction in a manner that is required, by the instruction description, to cause an Alignment interrupt, or to execute a prefixed instruction that crosses a 64-byte boundary. These cases are as follows.

- A Load/Store Multiple instruction that is executed in Little-Endian mode
- A Move Assist instruction that is executed in Little-Endian mode, unless the string length is zero
- A copy, paste, iwat, ldat, lhax, lwax, ldarx, lqarx, stwat, stdat, sthcx., stwcx., or stqcx. instruction that has an unaligned storage operand, unless execution of the instruction yields boundedly undefined results
- The operand(s) of a Load Atomic or Store Atomic instruction cross(es) a 32-byte boundary.
- A prefixed instruction that is at an effective address equal to 60 modulo 64.

An Alignment interrupt may occur when no higher priority exception exists and a data access cannot be performed for any of the following reasons.

- The storage operand of lfdp, lfdpx, stfdp, stfdpx, lxsihzx, or stxsihx is unaligned.
- The storage operand of lq or stq is unaligned.
- The storage operand of a Floating-Point Storage Access or VSX Storage Access instruction other than lfdp, lfdpx, stfdp, stfdpx, lxsihzx, lxsibzx, stxsihx, or stxsbx is not word-aligned.
- The storage operand of a Load/Store Multiple Word instruction is not word-aligned and the thread is in Big-Endian mode.
- The storage operand of a Load/Store Multiple Doubleword instruction is not doubleword-aligned and the thread is in Big-Endian mode.
- The storage operand of a Load/Store Multiple, lfdp, lfdpx, lxvi, lxvl, stfdp, stfdpx, stxvi, stxvl, or dcbz instruction is in storage that is Write Through Required or Caching Inhibited.
- The storage operand of a Move Assist instruction is in storage that is Write Through Required or Caching Inhibited and has length greater than zero.
- The storage operand of a Load or Store instruction is unaligned and is in storage that is Write Through Required or Caching Inhibited.
- The storage operand of a Storage Access instruction crosses a segment boundary, or crosses a boundary between virtual pages that have different storage control attributes.

The following registers are set:

- **SRR0**: Set to the effective address of the instruction that caused the interrupt.
- **SRR1**: 
  - 0x33 Set to 0.
  - 0x34 Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.
  - 0x35 Set to 1 if the instruction that caused the interrupt is a prefixed instruction that is at
an effective address equal to 60 modulo 64; otherwise set to 0.

36
Set to 0.

42:47
Set to 0.

Others
Loaded from the MSR.

MSR
See Figure 67.

DAR
Set to the effective address computed by the instruction, unless the instruction is a prefixed instruction at an effective address equal to 60 modulo 64, in which case set to an undefined value except as described in the next sentence. If the interrupt occurs in 32-bit mode the high-order 32 bits of the DAR are set to 0.

Execution resumes at effective address 0x0000_0000_0000_0600, possibly offset as specified in Figure 68.

---

**Programming Note**

If an Alignment interrupt occurs for a case in the second bulleted list above, the Alignment interrupt handler should emulate the instruction. The emulation must satisfy the atomicity requirements described in Section 1.4 of Book II.

If an Alignment interrupt occurs for a case in the first bulleted list above, the Alignment interrupt handler must not attempt to emulate the instruction, but instead should treat the instruction as a programming error.

---

**7.5.9 Program Interrupt**

A Program interrupt occurs when no higher priority exception exists and one of the following exceptions arises during execution of an instruction:

**Floating-Point Enabled Exception**

A Floating-Point Enabled Exception type Program interrupt is generated when the value of the expression

\[ (\text{MSRFE}0) \land (\text{MSRFE}1) \land \text{FPSCR}_{\text{FEX}} \]

is 1. FPSCR_{FEX} is set to 1 by the execution of a floating-point instruction that causes an enabled exception, including the case of a Move To FPSCR instruction that causes an exception bit and the corresponding enable bit both to be 1.

**Privileged Instruction**

The following applies if the instruction is executed when MSR_{PR} = 1.

A Privileged Instruction type Program interrupt is generated when execution is attempted of a privileged instruction, or of an mtsp or mfspr instruction that specifies an SPR that is privileged for the operation or that specifies PTCR, DAWRn, DAWRXn, or CIABR when those SPRs are ultravisor privileged for the operation.

The following applies if the instruction is executed when MSR_{HV PR} = 0b00 or when MSR_{S HV PR} = 0b010.

A Privileged Instruction type Program interrupt is generated when execution is attempted of an ultravisor privileged instruction, or of an mtsp or mfspr instruction that specifies an SPR, other than PTCR, DAWRn, DAWRXn, and CIABR, that is ultravisor privileged for the operation.

---

**Programming Note**

These are the only cases in which a Privileged Instruction type Program interrupt can be generated when MSR_{PR}=0. They can be distinguished from other causes of Privileged Instruction type Program interrupts by examining SRR1_{49} (the bit in which MSR_{PR} was saved by the interrupt).

---

**Trap**

A Trap type Program interrupt is generated when any of the conditions specified in a Trap instruction is met.

The following registers are set:

**SRR0**

For all Program interrupts except a Floating-Point Enabled Exception type Program interrupt, set to the effective address of the instruction that caused the corresponding exception.

For a Floating-Point Enabled Exception type Program interrupt, set as described in the following list.

- If MSR_{FE0 FE1} = 0b00, FPSCR_{FEX} = 1, and an instruction is executed that changes MSR_{FE0 FE1} to a nonzero value, set to the effective address of the instruction that the thread would have attempted
to execute next if no interrupt conditions were present.

**Programming Note**
Recall that all instructions that can alter MSR\textsubscript{FE0 FE} are context synchronizing, and therefore are not initiated until all preceding instructions have reported all exceptions they will cause.

- If MSR\textsubscript{FE0 FE} = 0b11, set to the effective address of the instruction that caused the Floating-Point Enabled Exception.
- If MSR\textsubscript{FE0 FE} = 0b01 or 0b10, set to the effective address of the first instruction that caused a Floating-Point Enabled Exception since the most recent time FFSR\textsubscript{FE} was changed from 1 to 0 or of some subsequent instruction.

**Programming Note**
If SRR0 is set to the effective address of a subsequent instruction, that instruction will not be beyond the first such instruction at which synchronization of floating-point instructions occurs. (Recall that such synchronization is caused by Floating-Point Status and Control Register instructions, as well as by execution synchronizing instructions and events.)

<table>

<td>Except for the cases in which SRR0 is not necessarily set to the effective address of the instruction that caused the exception (first and third bullets in the description of how SRR0 is set), set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction; for the cases in which SRR0 is not necessarily set to the effective address of the instruction that caused the exception, set to an undefined value.</td>
</tr>
<tr>
<td>35:36</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>42</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>43</td>
<td>Set to 1 for a Floating-Point Enabled Exception type Program interrupt; otherwise set to 0.</td>
</tr>
<tr>
<td>44</td>
<td>Set to 0.</td>
</tr>
</tbody>
</table>

**Others**
Loaded from the MSR.

Exactly one of bits 43, 45, and 46 is set to 1.

**MSR**
See Figure 67 on page 1261.

Execution resumes at effective address 0x0000_0000_0000_0700, possibly offset as specified in Figure 68.
7.5.10 Floating-Point Unavailable Interrupt

A Floating-Point Unavailable interrupt occurs when no higher priority exception exists, an attempt is made to execute a floating-point instruction (including floating-point loads, stores, and moves), and MSR_FFP=0.

The following registers are set:

<table>
<thead>
<tr>
<th>Register</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>SRR0</td>
<td>Set to the effective address of the instruction that caused the interrupt.</td>
</tr>
<tr>
<td>SRR1</td>
<td>Set to 0.</td>
</tr>
<tr>
<td></td>
<td>Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.</td>
</tr>
<tr>
<td>Others</td>
<td>Loaded from the MSR.</td>
</tr>
<tr>
<td>MSR</td>
<td>See Figure 67 on page 1261.</td>
</tr>
</tbody>
</table>

Execution resumes at effective address 0x0000_0000_0000_0800, possibly offset as specified in Figure 68.

Programming Note

In versions of the architecture that precede V. 2.05, the conditions that now cause a Hypervisor Emulation Assistance interrupt with HSRR145=0 instead caused an "Illegal Instruction type Program interrupt". This was a Program interrupt for which registers (SRR0, SRR1, and the MSR) were set as described above for the Privileged Instruction type Program interrupt, except that SRR144 was set to 1 and SRR145 was set to 0. Thus older operating systems have code to handle these conditions, at the Program interrupt vector location. For this reason, if a Hypervisor Emulation Assistance interrupt occurs with HSRR145=0 when the thread is not in hypervisor state, for an instruction that the hypervisor determines should be handled by the operating system, the hypervisor is expected to pass control to the operating system at the operating system’s Program interrupt vector location, with all registers (SRR0, SRR1, MSR, GPRs, etc.) set as if the instruction had caused a Privileged Instruction type Program interrupt, except with SRR144:45 set to 0b10. (The Hypervisor Emulation Assistance interrupt was added to the architecture in V. 2.05, and the Illegal Instruction type Program interrupt was removed from the architecture in V. 2.06. In V. 2.05 the Hypervisor Emulation Assistance interrupt was optional: implementations that supported it generated it as described in V. 2.06, and never generated an Illegal Instruction type Program interrupt; implementations that did not support it generated an Illegal Instruction type Program interrupt as described above.)
7.5.11 Decrementer Interrupt

A Decrementer interrupt occurs when no higher priority exception exists, a Decrementer exception exists, and MSR$_{EE}$=1.

The following registers are set:

<table>
<thead>
<tr>
<th>Register</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>SRR0</td>
<td>Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.</td>
</tr>
<tr>
<td>SRR1</td>
<td>33:36 Set to 0. 42:47 Set to 0.</td>
</tr>
<tr>
<td>Others</td>
<td>Loaded from the MSR.</td>
</tr>
</tbody>
</table>

MSR

See Figure 67 on page 1261.

Execution resumes at effective address 0x0000_0000_0000_0900, possibly offset as specified in Figure 68.

7.5.12 Hypervisor Decrementer Interrupt

A Hypervisor Decrementer interrupt occurs when no higher priority exception exists, a Hypervisor Decrementer exception exists, and the value of the following expression is 1.

$$(\text{MSR}_E \lor \neg (\text{MSR}_H) \lor \text{MSR}_P) \& \text{HDICE}$$

The following registers are set:

<table>
<thead>
<tr>
<th>Register</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>HSRR0</td>
<td>Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.</td>
</tr>
<tr>
<td>HSRR1</td>
<td>33:36 Set to 0. 42:47 Set to 0.</td>
</tr>
<tr>
<td>Others</td>
<td>Loaded from the MSR.</td>
</tr>
</tbody>
</table>

MSR

See Figure 67 on page 1261.

Execution resumes at effective address 0x0000_0000_0000_0980, possibly offset as specified in Figure 68.

7.5.13 Directed Privileged Doorbell Interrupt

A Directed Privileged Doorbell interrupt occurs when no higher priority exception exists, a Directed Privileged Doorbell exception is present, and MSR$_{EE}$=1. Directed Privileged Doorbell exceptions are generated when Directed Privileged Doorbell messages (see Chapter 11) are received and accepted by the thread.

The following registers are set:

<table>
<thead>
<tr>
<th>Register</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>SRR0</td>
<td>Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.</td>
</tr>
<tr>
<td>SRR1</td>
<td>33:36 Set to 0. 42:47 Set to 0.</td>
</tr>
<tr>
<td>Others</td>
<td>Loaded from the MSR.</td>
</tr>
</tbody>
</table>

MSR

See Figure 67 on page 1261.

Execution resumes at effective address 0x0000_0000_0000_0A00, possibly offset as specified in Figure 68.

7.5.14 System Call Interrupt

A System Call interrupt occurs when a System Call instruction is executed.

The following registers are set:

<table>
<thead>
<tr>
<th>Register</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>SRR0</td>
<td>Set to the effective address of the instruction following the System Call instruction.</td>
</tr>
<tr>
<td>SRR1</td>
<td>33:36 Set to 0. 42:43 Set to indicate the LEV value specified by the System Call instruction that caused the interrupt, as follows.</td>
</tr>
<tr>
<td>Others</td>
<td>Loaded from the MSR.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>LEV</th>
<th>SRR1 42:43</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>00</td>
</tr>
<tr>
<td>1</td>
<td>01</td>
</tr>
<tr>
<td>2</td>
<td>10</td>
</tr>
<tr>
<td>3*</td>
<td>undefined</td>
</tr>
<tr>
<td>*</td>
<td>reserved LEV value</td>
</tr>
</tbody>
</table>

Execution resumes at effective address 0x0000_0000_0000_0C00, possibly offset as specified in Figure 68.

Programming Note

Because the value of MSR$_{EE}$ is always 1 when the thread is in problem state, the simpler expression

$$(\text{MSR}_E \lor \neg (\text{MSR}_H)) \& \text{HDICE}$$

is equivalent to the expression given above.
### 7.5.15 Trace Interrupt

A Trace interrupt occurs when no higher priority exception exists and any instruction except `rfid`, `hrfid`, `urfid`, `rfscv`, or a Power-Saving Mode instruction is successfully completed, provided any of the following is true:

- the instruction is `mtmsr[d]` and MSRTE=0b10 when the instruction was initiated,
- the instruction is not `mtmsr[d]` and MSRTE=0b10,
- the instruction is a Branch instruction and MSRTE=0b01, or
- a CIABR match occurs.

Successful completion for an instruction means that the instruction caused no other interrupt. Thus a Trace interrupt never occurs for a System Call or System Call Vectored instruction, or for a Trap instruction that traps. The instruction that causes a Trace interrupt is called the “traced instruction”.

The following registers are set:

**SRR0**  
Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**SRR1**  
- 33  
Set to 1.  
- 34  
Set to 0 if the traced instruction is a word instruction and to 1 if the traced instruction is a prefixed instruction.  
- 35  
Set to 1 if the Trace interrupt is not the result of a CIABR match and the traced instruction is a Load instruction other than a Load String instruction with string length of 0 or is specified to be treated as a Load instruction; otherwise set to 0.  
- 36  
Set to 1 if the Trace interrupt is not the result of a CIABR match and the traced instruction is a Store instruction other than a Store String instruction with string length of 0 or is specified to be treated as a Store instruction; otherwise set to 0.

**SIAR**  
For all Trace interrupts other than those caused by a CIABR match, set to the effective address of the traced instruction; for Trace interrupts caused by a CIABR match, not modified if MSRTE=0b00; otherwise undefined.

**SDAR**  
For all Trace interrupts other than those caused by a CIABR match, set to the effective address of the storage operand (if any) of the traced instruction; for Trace interrupts caused by a CIABR match, not modified if MSRTE=0b00; otherwise undefined.

If the state of the Performance Monitor is such that the Performance Monitor may be altering the SIAR and SDAR (i.e., if MMCR0PMAE=1), the contents of the SIAR and SDAR are undefined for the Trace interrupt and may change even when no Trace interrupt occurs.

**MSR**  
See Figure 67 on page 1261.

Execution resumes at effective address 0x0000_0000_0000_00D0, possibly offset as specified in Figure 68. For a Trace interrupt resulting from execution of an instruction that modifies the value of MSRIR, MSRD, MSRHV, LPCRAIL, or LPCRHAIL, the Trace interrupt vector location is based on the modified values.

---

**Programming Note**  
An attempt to execute an `sc` instruction with LEV=1 or LEV=2 in problem state, or an attempt to execute an `sc` instruction with LEV=2 in privileged non-hypervisor state, should be treated as a programming error.

An attempt to execute an `sc` instruction with LEV=2 when SMFCTRLE=0 should be treated as a programming error.

---

**Programming Note**  
An attempt to execute an `sc` instruction with LEV=1 or LEV=2 in problem state, or an attempt to execute an `sc` instruction with LEV=2 in privileged non-hypervisor state, should be treated as a programming error.

---

**Programming Note**  
Bit 33 is set to 1 for historical reasons.

---

**Programming Note**  
The following instructions are not traced.

- `rfid`
- `hrfid`
- `urfid`
- `rfscv`
- `sc`, `scv`, and Trap instructions that trap
- Power-Saving Mode instructions
- other instructions that cause interrupts (other than Trace interrupts)
- the first instructions of any interrupt handler (applies to Branch and Single Step tracing; CIABR matches may still occur)
- instructions that are emulated by software

In general, interrupt handlers can achieve the effect of tracing these instructions.
7.5.16 Hypervisor Data Storage Interrupt (HDSI)

A Hypervisor Data Storage interrupt occurs when no higher priority exception exists, either the thread is not in hypervisor state or an unsupported MMU configuration has been found or the access has been prevented by a problem in partition-scoped Radix Tree translation, and either

(a) HPT translation is being performed, VPM=0, LPCR\textsubscript{KBV}=1, and a Virtual Storage Page Class Key Protection exception exists or

(b) HPT translation is being performed and either a PRTE, STEG, or PTEG access causes a Secure Memory Protection exception or the value of the expression \((\neg\text{MSRDR}) \land (\text{VPM} \lor \text{PRTEV} \lor \text{MSRDR})\) is 1, and a data access cannot be performed, or

(c) Radix Tree translation is being performed and either a page fault or an unsupported MMU configuration in the PATE (unsupported value of RTS or RPDS) occurs attempting to access the LPID=0 process table or partition-scoped translation other than for the LPID=0 process table prevents an access from being performed

for any of the following reasons that can occur in the respective translation state.

- HR=0, data address translation is enabled (MSR\textsubscript{DR}=1) and the virtual address of any byte of the storage location specified by a \textit{Load}, \textit{Store}, \textit{icbi}, \textit{dcbz}, \textit{dcbst}, or \textit{dcbf} instruction cannot be translated to a real address because no valid PTE was found for the VPM translation.
- HR=1 and the guest real address of any byte of the storage location specified by a \textit{Load}, \textit{Store}, \textit{icbi}, \textit{dcbz}, \textit{dcbst}, or \textit{dcbf} instruction cannot be translated to a host real address because no valid PTE was found in the partition-scoped page table.
- The guest real address of a page directory entry, page table entry, or process table entry could not be translated when HR=1; or the virtual address of a process table entry or segment table entry group could not be translated when VPM=1 and HR=0.
- An unsupported MMU configuration is found. In addition to an unsupported radix tree configuration found for the partition-scoped tables, this type of exception will also be reported outside of hypervisor or ultravisor real mode for translation mode mismatches including UPRT=0 when HR=1, LPID=0 if MSR\textsubscript{HIV}=0 when HR=1, and HR=0 for LPID=0 when HR=1 for another partition ID. (Note that these conditions may not be detected until the associated values are about to cause a functional problem for the processor.)

- A reference or change bit update in a partition-scoped PTE cannot be performed (including for the process-scoped PDE or PTE or process table entry for a radix guest.

When reporting failure to set a reference or change bit for a table entry, whether the change bit must be set is inferred from whether the access is reported to be a store. (A load may report store if, when attempting to set the reference bit, the update of the change bit in the partition-scoped PTE mapping the process-scoped PTE fails.) Behavior is similar for access authority failures.

- HR=0, data address translation is disabled (MSR\textsubscript{DR}=0), and the virtual address of any byte of the storage location specified by a \textit{Load}, \textit{Store}, \textit{icbi}, \textit{dcbz}, \textit{dcbst}, or \textit{dcbf} instruction cannot be translated to a real address by means of the virtual real addressing mechanism.

The effective address specified by a \textit{lq}, \textit{stq}, \textit{lwat}, \textit{idat}, \textit{ilbarx}, \textit{ilharp}, \textit{ilwarx}, \textit{ldarx}, \textit{lqarx}, \textit{stdat}, \textit{stbcx}, \textit{stbch}, \textit{stwcx}, \textit{stwcx}, or \textit{stqcx}, instruction refers to storage that is Write Through Required or Caching Inhibited; or the effective address specified by a \textit{copy} or \textit{paste}. instruction refers to storage that is Caching Inhibited; or the effective address specified by a \textit{lwat}, \textit{idat}, \textit{stwat}, or \textit{stdat} instruction refers to storage that is Guarded.

- An accelerator is specified as the source of a \textit{copy} instruction or an attempt is made to access an accelerator that is not properly configured for the software’s use; HR=0 only.

The access violates storage protection. In addition to the legacy VPM cases (including those for Secure Memory Protection), this includes mismatches in access authority in which the process-scoped PTE permits the access but the partition-scoped PTE does not and Secure Memory Protection for a radix guest. It also includes lack of necessary authority for accesses to process-scoped tables (which cannot happen when HR=0), for example lack of write authority to set a reference bit in the process-scoped PTE (and Secure Memory Protection here as well). (In such a case, the “access” reported as failing would be the access to the process-scoped table. The
A Hypervisor Data Storage interrupt also occurs when no higher priority exception exists and an attempt is made to execute a Load Atomic or Store Atomic instruction specifying an invalid function code.

If a stbcx, sthcx, stwcx, stdcx, or stqcx instruction would not perform its store in the absence of a Hypervisor Data Storage interrupt, and either (a) the specified effective address refers to storage that is Write Through Required or Caching Inhibited, or (b) a non-conditional Store to the specified effective address would cause a Hypervisor Data Storage interrupt, it is implementation-dependent whether a Hypervisor Data Storage interrupt occurs.

If the XER specifies a length of zero for an indexed Move Assist instruction, a Hypervisor Data Storage interrupt does not occur.

The following registers are set:

- **HSRR0**: Set to the effective address of the instruction that caused the interrupt.
- **HSRR1**
  - **33**: Set to 0.
  - **34**: Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.
  - **35:36**: Set to 0.
  - **42:47**: Set to 0.
  - **Others**: Loaded from the MSR.
- **HDSISR**
  - **32**: Set to 0.
  - **33**: Set to 1 if the translation for an attempted access is not found in the Page Table; otherwise set to 0.
  - **34:35**: Set to 0.
  - **36**: Set to 1 if the access is not permitted by Figure 45 or the read or read/write bits in Figure 46 as appropriate; otherwise set to 0.
  - **37**: Set to 1 if the access is due to a lq, stq, lwat, ldat, ldarx, lwarx, lwrcx, lwqcx, lqcx, stwat, stdat, stbcx, sthcx, stwcx, stdcx, or stqcx instruction that addresses storage that is Write Through Required or Caching Inhibited; or if the access is due to a copy or paste instruction that addresses storage that is caching inhibited; or if the access is due to a lwat, ldat, stwat, or stdat instruction that addresses storage that is Guarded; otherwise set to 0.
  - **38**: Set to 1 by an explicit access for a Store, dcbz, or Load/Store Atomic instruction; set to 1 when a process-scoped PTE update fails due to a lack of write authority or the inability to set the change bit in the partition-scoped PTE; otherwise set to 0.
  - **39:40**: Set to 0.
  - **41**: Set to 1 if a Data Address Watchpoint match occurs; otherwise set to 0.
  - **42**: Set to 1 if the access is not permitted by virtual page class key protection; otherwise set to 0.
  - **43**: Set to 1 if the access is not permitted by Secure Memory Protection; otherwise set to 0.
  - **44**: Set to 1 if an unsupported MMU configuration is found during the translation process.
  - **45**: Set to 1 if an attempt to atomically set a reference or change bit fails; otherwise set to 0.

Programming Note

When an attempt to execute a Load Atomic or Store Atomic instruction containing an invalid function code (see Figures 3 and 4 in Book II) causes an HDSI, the condition is very similar to an invalid form of an instruction. As a result, this instance of an HDSI makes to atomically set Reference and Change bit updates.

The number of attempts hardware makes to atomically set reference and change bits before triggering this exception is implementation dependent. The POWER9 processor makes no attempt. Software may still support the atomic update programming model to get performance benefits such as those described in Section 6.7.12.
tion-caused exceptions. See Section 4.4, “Copy-Paste Facility”, in Book II for details. Additional information may be retained by the platform if the accelerator is not properly configured.

61

Set to 1 if an attempt is made to execute a Load Atomic or Store Atomic instruction specifying an invalid function code; otherwise set to 0.

62:63

Set to 0.

**HDAR**

Set to the effective address or portion of the VPN of a storage element, or undefined, as described in the following list. The list should be read from the top down; the HDAR is set as described by the first item that corresponds to an exception that is reported in the HDSISR. For example, if a Load Word instruction causes a storage protection violation and a Data Address Watchpoint match (and both are reported in the HDSISR), the HDAR is set to the effective address of a byte in the first aligned doubleword for which access was attempted in the page that caused the exception.

- undefined, for Load Atomic or Store Atomic instruction specifying an invalid function code
- undefined, when HDSISR60=1
- least significant 64 bits of the VA of the table entry or group when a process table entry or segment table entry group virtual address cannot be translated in Paravirtualized HPT mode with VPM=1.
- EA, when a Hypervisor Data Storage exception occurs for reasons other than a Data Address Watchpoint match
  - a byte in the block that caused the exception, for a Cache Management instruction
  - a byte in the first aligned doubleword for which access was attempted in the page that caused the exception, for a Load or Store instruction (“first” refers to address order; see Section 7.7).
- the first byte of overlap between the operand and the matching watched range, for a Data Address Watchpoint match

For the cases in which the HDAR is specified above to be set to an effective address, if the interrupt occurs in 32-bit mode the high-order 32 bits of the HDAR are set to 0.

**ASDR**

When HR=0, loaded with VSID, B, Ks, Kp, N, C, L, and LP values from the segment descriptor that translated the access or indicated the base of the table, or undefined, as described in the following list. When HR=1 (nested translation is taking place), loaded with the guest real address down to bit 51 of a storage element or table entry, or undefined, as described in the following list. The list should be read from the top down; the ASDR is set as described by the first item that corresponds to an exception that is reported in the HDSISR.

- undefined, for Load Atomic or Store Atomic instruction specifying an invalid function code
- undefined, when HDSISR60=1
- the guest real page address of the table entry when a process table or process-scoped page directory or page table entry guest real address cannot be translated or the VSID of the table entry (group) when a Process Table Entry or Segment Table Entry Group virtual address cannot be translated (the rest of the segment descriptor is implied, or, for the base page size, comes from the Partition Table Entry or Process Table Entry, respectively).
- the guest real address of the process-scoped PDE or PTE or process table entry when a reference or change bit in the partition-scoped PTE mapping the process-scoped PDE or PTE or process table entry cannot be set atomically
- the guest real address of the storage element when a reference or change bit in the partition-scoped PTE cannot be set atomically
- the guest real address of the storage element, process table entry, page directory entry, or page table entry (depending on which partition-scoped table has the flaw) for an unsupported radix tree configuration for the partition-scoped tables (the effective address for other cases of the invalid MMU configuration exception is found in the HDAR)
- the guest real address of the process-scoped PTE when an attempt is
made to set a reference or change bit without write authority in the partition-scoped PTE that maps it

- the guest real address or segment descriptor associated with the specified storage element when a Hypervisor Data Storage exception occurs for reasons other than a Data Address Watchpoint match
- undefined, for a Data Address Watchpoint match, unsupported MMU configuration, or accesses to storage that is Caching Inhibited or Write Through Required by the instructions that are prohibited from making such accesses.

If multiple Hypervisor Data Storage exceptions occur for a given effective address, any one or more of the bits corresponding to these exceptions may be set to 1 in the HDSISR. If the HDSISR reports other exceptions together with a Virtualized Page Class Key Storage Protection exception that occurs when LPCRKBV=1 and Virtualized Partition Memory is disabled by VPM=0, the other exceptions are actually DSIs.

## Programming Note

A Virtual Page Class Key Storage Protection exception that occurs with LPCRKBV=1 and Virtualized Partition Memory disabled by VPM=0 identifies an access that must be emulated by the hypervisor. When it is reported together with other exceptions in the HDSISR, the hypervisor should service the Virtual Page Class Key Storage Protection exception first. This is in part because the operating system may be using some PTE fields for non-architected purposes, which could in turn cause spurious exceptions to be reported.

Execution resumes at effective address 0x0000_0000_0000_0E00, possibly offset as specified in Figure 68.

### 7.5.17 Hypervisor Instruction Storage Interrupt (HISI)

A Hypervisor Instruction Storage interrupt occurs when no higher priority exception exists, either the thread is not in hypervisor state or an unsupported MMU configuration has been found or the access has been prevented by a problem in partition-scoped Radix Tree translation, and either

(a) HPT translation is being performed and either a PRTE, STEG, or PTEG access causes a Secure Memory Protection exception or the value of the expression (~MSRIR) | (VPM & PRTEV & MSRIR) is 1, and the next instruction to be executed cannot be fetched, or

(b) Radix Tree translation is being performed and either a page fault or an unsupported MMU configuration in the PATE (unsupported value of RTS or RPDS) occurs attempting to access the LPID=0 process table or partition-scoped translation other than for the LPID=0 process table prevents the next instruction to be executed from being fetched

for any of the following reasons that can occur in the respective translation state.

- Instruction address translation is enabled (MSRIR=1) and the virtual address cannot be translated to a real address because no valid PTE was found for the VPM translation.
- HR=1 and the guest real address of the instruction cannot be translated to a host real address because no valid PTE was found in the partition-scoped page table.
- The guest real address of a page directory entry or process table entry could not be translated when HR=1; or the virtual address of a process table entry or segment table entry group could not be translated when VPM=1 and HR=0.
- An unsupported MMU configuration is found. In addition to an unsupported radix tree configuration found for the partition-scoped tables, this type of exception will also be reported outside of hypervisor or ultravisor real mode for translation mode mismatches including UPRT=0 when HR=1, LPID=0 if MSRIRV=0 when HR=1, and HR=0 for LPID=0 when HR=1 for another partition ID. (Note that these conditions may not be detected until the associated values are about to cause a functional problem for the processor.)
- A reference or change bit update in a partition-scoped PTE cannot be performed (including for the process-scoped PDE or PTE or process table entry for a radix guest.
- HR=0, instruction address translation is disabled (MSRIR=0), and the virtual address cannot be translated to a real address by means of the virtual real addressing mechanism.
- The fetch violates storage protection. In addition to the legacy VPM cases (including those for Secure Memory Protection), this includes mismatches in access authority in which the process-scoped PTE permits the access but the partition-scoped PTE does not and Secure Memory Protection for a radix guest. It also includes lack of necessary authority for accesses to process-scoped tables (which cannot happen when HR=0), for example lack of write authority to set a reference bit in the process-scoped PTE (and Secure Memory Protection here as well). (In such a case, the “access” reported as failing would be the access to the process-scoped table. The
ASDR would provide the guest real address of the table entry.)

- The instruction is a prefixed instruction and is in storage that is Caching Inhibited.

The following registers are set:

**HSRR0**
- Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present (if the interrupt occurs on attempting to fetch a branch target, HSRR0 is set to the branch target address).

**HSRR1**
- **33** Set to 1 if the translation for an attempted access is not found in the Page Table; otherwise set to 0.
- **34** Set to 0.
- **35** Set to 1 if the access is to No-execute (as indicated by the N bit in the segment table entry and HPT PTE or the exec bit in the EAA field of the Radix PTE) or Guarded storage, or is to Caching Inhibited storage and is for a prefixed instruction; otherwise set to 0.
- **36** Set to 1 if the access is not permitted by Figure 45 or the execute bit in Figure 46 as appropriate; otherwise set to 0.
- **42** Set to 1 if the access is not permitted by virtual page class key protection; otherwise set to 0.
- **43** Set to 1 if the access is not permitted by Secure Memory Protection; otherwise set to 0.
- **44** Set to 1 if an unsupported MMU configuration is found during the translation process.
- **45** Set to 1 if an attempt to atomically set a reference or change bit fails; otherwise set to 0.

**Others**
- Loaded from the MSR.

**HDAR**
- Set to the least significant 64 bits of the VA of a table entry or group when HR=0 and a process table entry or segment table entry group virtual address cannot be translated and VPM=1. May be set spuriously in other cases.

**ASDR**
- When HR=0, loaded with VSID, B, Ks, Kp, N, C, L, and LP values from the segment descriptor that translated the access or indicated the base of the table, or undefined, as described in the following list. When HR=1 (nested translation is taking place), loaded with the guest real address down to bit 51 of the instruction or table entry, or undefined, as described in the following list.

- the guest real address of the table entry when a process table or process-scoped page directory or page table entry guest real address cannot be translated or the VSID of the table entry (group) when a Process Table Entry or Segment Table Entry Group virtual address cannot be translated (the rest of the segment descriptor is implied, or, for the base page size, comes from the Partition Table Entry or Process Table Entry, respectively).
- the guest real address of the process-scoped PDE or PTE or process table entry when a reference or change bit in the partition-scoped PTE mapping the process-scoped PDE or PTE or process table entry cannot be set atomically
- the guest real address of the instruction when a reference or change bit in the partition-scoped PTE cannot be set atomically
- the guest real address of the instruction, process table entry, page directory entry, or page table entry (depending on which partition-scoped table has the flaw) for an unsupported radix tree configuration for the partition-scoped tables (the effective address for other cases of the invalid MMU configuration exception will be found in HSRR0)
- the guest real address of the process-scoped PTE when an attempt is made to set a reference bit without

**Programming Note**

The number of attempts hardware makes to atomically set reference and change bits before triggering this exception is implementation dependent. The POWER9 processor makes no attempt. Software may still support the atomic update programming model to get performance benefits such as those described in Section 6.7.12.
write authority in the partition-scoped PTE that maps it
- the guest real address or segment descriptor associated with the instruction that the thread would have attempted to execute next if no interrupt conditions were present (partition-scoped page fault or protection exception)
- undefined for unsupported MMU configuration

**MSR** See Figure 67.

If multiple Hypervisor Instruction Storage exceptions occur due to attempting to fetch a single instruction, any one or more of the bits corresponding to these exceptions may be set to 1 in HSRR1.

Execution resumes at effective address 0x0000_0000_0000_0E10, possibly offset as specified in Figure 68.

### 7.5.18 Hypervisor Emulation Assistance Interrupt

A Hypervisor Emulation Assistance interrupt is generated when execution is attempted of an illegal instruction, or of a reserved instruction or an instruction that is not provided by the implementation. It is also generated under the following conditions.

- When MSRRHV PR=0b00 and LPCR EVIRT=1, execution is attempted of a hypervisor privileged instruction, or of a mtspr or mfspr instruction that specifies an SPR that is hypervisor privileged for the operation or that specifies PTCR, DAWRn, DAWRXn, or CIABR when those SPRs are ultravisor privileged for the operation.
- When MSRRHV PR = 0b010, execution is attempted of a mtspr or mfspr instruction that specifies PTCR, DAWRn, DAWRXn, or CIABR when those SPRs are ultravisor privileged for the operation.
- When MSR PR=1, execution is attempted of an mtspr or mfspr instruction that specifies SPR with spr0=0 that is not provided by the implementation.
- When MSR PR=0, execution is attempted of an mtspr or mfspr instruction that specifies SPR 0, 4, 5, or 6.
- When MSR PR=0 and LPCREVIRT=1, execution is attempted of an mtspr or mfspr instruction that specifies an SPR other than 0, 4, 5, or 6 that is not provided by the implementation.

A Hypervisor Emulation Assistance interrupt may be generated when execution is attempted of an instruction that is in invalid form or that is treated as if the instruction form were invalid.

The following registers are set:

**HSRR0** Set to the effective address of the instruction that caused the interrupt.

**HSRR1**
- 33 Set to 0.
- 34 Set to 0 if the instruction that caused the interrupt is a word instruction (or a prefixed instruction when prefixed instructions are unavailable based on the PCR setting) and to 1 if the instruction that caused the interrupt is a prefixed instruction.
- 35:36 Set to 0.
- 42:44 Set to 0.
- 45 Set to 1 for an attempt, when MSRRHV PR = 0b00 and LPCR EVIRT=1, to execute a hypervisor privileged instruction or an mtspr or mfspr instruction that specifies an SPR that is hypervisor privileged for the operation or that specifies PTCR, DAWRn, DAWRXn, or CIABR when they are ultravisor privileged for the operation, or for an attempt when MSRRHV PR = 0b010 to execute an mtspr or mfspr instruction that specifies PTCR, DAWRn, DAWRXn, or CIABR when they are ultravisor privileged for the operation; otherwise set to 0.
- 46:47 Set to 0.
- Others Loaded from the MSR.

**MSR** See Figure 67 on page 1261.

**HEIR** Set to a copy of the instruction that caused the interrupt.

If the interrupt is caused by an attempt to execute an invalid form of a hypervisor privileged instruction when MSRRHV PR = 0b00 and LPCR EVIRT=1, it is implementation dependent whether HSRR145 is set to 0 (reflecting the invalid instruction form) or to 1 (reflecting the privilege violation).

Execution resumes at effective address 0x0000_0000_0000_0E40, possibly offset as specified in Figure 68.
This Programming Note illustrates how Hypervisor Emulation Assistance interrupts should be handled by software, including in environments that support nested hypervisors. For simplicity, this Programming Note ignores effects of the SMF facility (equivalently, assumes that SMFCtrlLE=0).

In this Note, “the hypervisor” may be the hypervisor to which hardware passes control when a Hypervisor Emulation Assistance interrupt occurs or, in an environment that supports nested hypervisors, may be a nested hypervisor. The hypervisor to which hardware passes control when a Hypervisor Emulation Assistance interrupt occurs is here called the “level 0 hypervisor,” and is the only level of hypervisor that runs with MSR HV PR=0b10 and that can access hypervisor resources directly; nested hypervisors run with MSR HV PR=0b00 and their attempts to access hypervisor resources are virtualized by a higher-level hypervisor as described below. In this Note, the hypervisor receiving the Hypervisor Emulation Assistance interrupt (which may have been passed from a higher-level hypervisor as described below) is called the “level N hypervisor.” This Note assumes that LPCREVIRT=1 if nested hypervisors are used. (A Hypervisor Emulation Assistance interrupt can set HSRR145 to 1 only when LPCREVIRT=1.) Higher level numbers correspond to lower level hypervisors.

In the description immediately below, it is assumed that nested hypervisors (if any) are new versions of the existing hypervisor, and that the purpose of the nesting is to test the nested hypervisors before using them as level 0 hypervisors.

When a Hypervisor Emulation Assistance interrupt is received by the level N hypervisor, the cases and their suggested handling are as follows.

- The program that caused the interrupt is the level N hypervisor itself.
  - HSRR145=0: Emulate the instruction, recover from the error, or terminate this hypervisor, as appropriate.
  - HSRR145=1: Cannot occur for N=0; will not occur for N>0 if the hypervisor nesting software is written correctly.

- The program that caused the interrupt is not the level N hypervisor.
  - The program most recently dispatched by the level N hypervisor is a program.
    - HSRR145=0: Pass control to the level N+1 hypervisor as if the instruction had caused a Hypervisor Emulation Assistance interrupt (with HSRR145=0) to that hypervisor.
    - HSRR145=1: Either terminate the operating system or pass control to the operating system as if the instruction had caused an “Illegal Instruction type Program interrupt” as described in a Programming Note near the end of Section 7.5.9.
  - The program most recently dispatched by the level N hypervisor is an application program.
    - HSRR145=0: Emulate the instruction if appropriate; otherwise terminate the application program.
    - HSRR145=1: Cannot occur.

The preceding description implicitly assumes that any nested hypervisors being tested will, when run at level 0, be run on processors that support the same version of the architecture as the processor on which they are being tested. If instead they will be run on processors that support a newer version of the architecture, the level 0 hypervisor should behave as described above if the interrupt is caused by an instruction that is unchanged between the two architecture versions. However, if the interrupt is caused by an instruction that differs between the two architecture versions (e.g., an instruction that is added by the newer version of the architecture), the level 0 hypervisor should emulate the behavior of the newer processor, rather than, for example, passing the interrupt to a level 1 hypervisor.

Other uses of nested hypervisors are also possible. For example, software that is designed to interact, nearly simultaneously, with the hypervisor instance that is running on each of many processors could be tested on a single processor by running multiple level 1 hypervisors under a single level 0 hypervisor.

It is expected that in practice there will be at most two levels of nested hypervisor (i.e., N≤2). (For example, two levels are needed in the case described in detail above, to test the ability of the nested hypervisors at level 1 to support nested hypervisors.)
7.5.19 Hypervisor Maintenance Interrupt

A Hypervisor Maintenance interrupt occurs when no higher priority exception exists, a Hypervisor Maintenance exception exists (a bit in the HMER is set to one), the exception is enabled in the HMEER, and the value of the following expression is 1.

\[(MSREE \mid \neg(MSRHV))\]

The following registers are set:
- **HSRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **HSRR1**: Settings depend on the situation.
- **Others**: Loaded from the MSR.

If a Hypervisor Emulation Assistance interrupt occurs with HSRR1_{45}=0 when the thread is not in hypervisor state, for an instruction that the hypervisor does not emulate, the hypervisor should pass control to the operating system as if the instruction had caused an "Illegal Instruction type Program interrupt", as described in a Programming Note near the end of Section 7.5.9, “Program Interrupt” on page 1272.

Similarly, if a Hypervisor Emulation Assistance interrupt occurs with HSRR1_{45}=1 when the thread is in privileged non-hypervisor state, for an instruction that the hypervisor does not virtualize, the hypervisor should pass control to the operating system as if the instruction had caused a Privileged Instruction type Program interrupt, as described in another Programming Note near the end of Section 7.5.9, “Program Interrupt” on page 1272.

The exception bits in the HMER are sticky; that is, once set to 1 they remain set to 1 until they are set to 0 by an **mthmer** instruction.

Execution resumes at effective address 0x0000_0000_0000_0E60.

7.5.20 Directed Hypervisor Doorbell Interrupt

A Directed Hypervisor Doorbell interrupt occurs when no higher priority exception exists, a Directed Hypervisor Doorbell exception is present, and the value of the following expression is 1.

\[(MSREE \mid \neg(MSRHV))\]

Directed Hypervisor Doorbell exceptions are generated when Directed Hypervisor Doorbell messages (see Chapter 11) are received and accepted by the thread.

The following registers are set:
- **HSRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **HSRR1**: Settings depend on the situation.
- **Others**: Loaded from the MSR.

**Programming Note**

If an implementation uses the HMER to record that a readable resource, such as the Time Base, has been corrupted, then, because the HMI is disabled in the hypervisor state, it is necessary for the hypervisor to check HMER after reading that resource to be sure an error has not occurred.

**Programming Note**

Because the value of MSREE is always 1 when the thread is in problem state, the simpler expression

\[(MSRE\mid \neg(MSRHV))\]

is equivalent to the expression given above.
7.5.21 Hypervisor Virtualization Interrupt

A Hypervisor Virtualization interrupt occurs when no higher priority exception exists, a Hypervisor Virtualization exception exists, and the value of the following equation is 1.

\[(\text{MSREE} \lor \neg (\text{MSRHV}) \lor \text{MSRPR}) \land \text{HVICE}\]

The occurrence of the interrupt does not cause the exception to cease to exist.

**HSRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**HSRR1**
- **33:36** Set to 0.
- **42:47** Set to 0.
- **Others** Loaded from the MSR.

**MSR** See Figure 67 on page 1261.

Execution resumes at effective address 0x0000_0000_0000_0E80, possibly offset as specified in Figure 68.

Programming Note
Because the value of MSREE is always 1 when the thread is in problem state, the simpler expression \((\text{MSREE} \lor \neg (\text{MSRHV}))\) is equivalent to the expression given above.

7.5.23 Vector Unavailable Interrupt

A Vector Unavailable interrupt occurs when no higher priority exception exists, an attempt is made to execute a Vector instruction (including Vector loads, stores, and moves), and MSRVEC=0.

The following registers are set:

**SRR0** Set to the effective address of the instruction that caused the interrupt.

**SRR1**
- **33** Set to 0.
- **34** Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.
- **35:36** Set to 0.
- **42:47** Set to 0.
- **Others** Loaded from the MSR.

**MSR** See Figure 67 on page 1261.

Execution resumes at effective address 0x0000_0000_0000_0F20, possibly offset as specified in Figure 68.

7.5.24 VSX Unavailable Interrupt

A VSX Unavailable interrupt occurs when no higher priority exception exists, an attempt is made to execute a VSX instruction (including VSX loads, stores, and moves), and MSRVSX=0.

The following registers are set:

**SRR0** Set to the effective address of the instruction that caused the interrupt.

**SRR1**
- **33** Set to 0.
- **34** Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.
- **35:36** Set to 0.
- **42:47** Set to 0.
- **Others** Loaded from the MSR.

**MSR** See Figure 67 on page 1261.

Execution resumes at effective address 0x0000_0000_0000_0F00, possibly offset as specified in Figure 68.
7.5.25 Facility Unavailable Interrupt

A Facility Unavailable interrupt occurs when no higher priority exception exists, and one of the following occurs.
- A facility is accessed in problem state when it has been made unavailable by the FSCR.
- A Performance Monitor register is accessed or a \texttt{clbrb} or \texttt{mfbrbe} instruction is executed in problem state when it has been made unavailable by MMCR0.

The following registers are set:

<table>
<thead>
<tr>
<th>Register</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{SRR0}</td>
<td>Set to the effective address of the instruction that caused the interrupt.</td>
</tr>
<tr>
<td>\texttt{SRR1}</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>33</td>
<td>Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.</td>
</tr>
<tr>
<td>34</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>35:36</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>42:47</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>Others</td>
<td>Loaded from the MSR.</td>
</tr>
</tbody>
</table>

Execution resumes at effective address 0x0000_0000_0000_0F40, possibly offset as specified in Figure 68.

7.5.26 Hypervisor Facility Unavailable Interrupt

A Hypervisor Facility Unavailable interrupt occurs when no higher priority exception exists, and one of the following occurs.
- A facility is accessed in problem or privileged non-hypervisor states when it has been made unavailable by the HFSCR.
- The \texttt{stop} instruction is executed in privileged non-hypervisor state when any of the following conditions exist.
  - $\text{PSSCR}_{\text{MTL}} > \text{PSSCR}_{\text{PSLL}}$
  - $\text{PSSCR}_{\text{RL}} > \text{PSSCR}_{\text{PSLL}}$

The following registers are set:

<table>
<thead>
<tr>
<th>Register</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{HSRR0}</td>
<td>Set to the effective address of the instruction that caused the interrupt.</td>
</tr>
<tr>
<td>\texttt{HSRR1}</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>33</td>
<td>Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.</td>
</tr>
<tr>
<td>34</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>35:36</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>42:47</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>Others</td>
<td>Loaded from the MSR.</td>
</tr>
</tbody>
</table>

Execution resumes at effective address 0x0000_0000_0000_0F60, possibly offset as specified in Figure 68.
The Hypervisor Facility Unavailable interrupt handler should either (a) make the facility, the attempted use of which caused the interrupt, available, or (b) pass control to the operating system as if the instruction that caused the interrupt had instead caused an "Illegal Instruction type Program interrupt", as described in a Programming Note near the end of Section 7.5.9. Specifically, for choice (b) the hypervisor should pass control to the operating system at the operating system’s Program interrupt vector location, with all registers (SRR0, SRR1, MSR, GPRs, etc.) set as if the instruction had caused a Privileged Instruction type Program interrupt, except with SRR1_{44:45} set to 0b10. (This behavior is the same as that provided by the Hypervisor Emulation Assistance interrupt handler when that interrupt is caused by an illegal instruction or by \textit{mt/fspr} specifying an undefined SPR number.) In general this behavior by the Hypervisor Facility Unavailable interrupt handler provides to the operating system the appearance that the instructions in the facility are illegal instructions and that the SPRs in the facility correspond to undefined SPR numbers. The cases in which it does not provide this appearance are as follows.

1. **privileged instruction executed in problem state**
   Because Privileged Instruction type Program interrupt has higher priority than Hypervisor Facility Unavailable interrupt, an attempt in problem state to execute a privileged instruction made unavailable by the HFSCR will cause a Privileged Instruction type Program interrupt to the operating system, rather than a Hypervisor Facility Unavailable interrupt, so the hypervisor will not have opportunity to make the instruction appear to be illegal. (It may be useful to note that the handling described in choice (b) above together with the behavior of this case provides behavior, in problem state, that is equivalent to the behavior that would be obtained by making the facility unavailable by means of the PCR.)

2. **\textit{mt/fspr} executed in privileged non-hypervisor state when LPCREVIRT=0**
   \textit{mt/fspr} specifying an undefined SPR number (other than 0, 4, 5, 6) and executed in privileged non-hypervisor state when LPCREVIRT=0 will be treated as a no-op. If instead the SPR number is defined and the SPR is made unavailable by the HFSCR a Hypervisor Facility Unavailable interrupt will occur, and there is no easy way for the interrupt handler to determine that the interrupting instruction is \textit{mt/fspr} and hence should be treated as a no-op. (Hypervisor Facility Unavailable interrupt does not set HEIR.) Passing control to the operating system’s Program interrupt handler in the manner described above is preferable to incurring the software complexity and performance cost of emulating the no-op behavior.

### 7.5.27 System Call Vectored Interrupt

A System Call Vectored interrupt occurs when a System Call Vectored instruction is executed.

The following registers are set:

- **LR**
  Set to the effective address of the instruction following the System Call Vectored instruction.

- **CTR**
  - 33:36: undefined
  - 42:47: undefined

- **Others**
  Loaded from corresponding bits of the MSR.

- **MSR**
  See Figure 67 on page 1261.

Execution resumes at the effective address specified in Figure 68.
7.5.28 Directed Ultravisor Doorbell Interrupt

A Directed Ultravisor Doorbell interrupt occurs when no higher priority exception exists, SMFCTRL\textsubscript{LE}=1, a Directed Ultravisor Doorbell exception is present, and the value of the following expression is 1.

\[(\text{MSR}_{\text{EE}} \mid \neg (\text{MSR}_{\text{S HV PR}}=0b110))\]

Directed Ultravisor Doorbell exceptions are generated when Directed Ultravisor Doorbell messages (see Chapter 11) are received and accepted by the thread.

The following registers are set:

- **USRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **USRR1**: Set to 0.
  - 33:36: Set to 0.
  - 42:47: Set to 0.
  - Others: Loaded from the MSR.

**MSR**: See Figure 67 on page 1261.

Execution resumes at effective address 0x0000_0000_0000_0FA0.

7.6 Partially Executed Instructions

If a Data Storage, Data Segment, Alignment, system-caused, or imprecise exception occurs while a Load or Store instruction is executing, the instruction may be aborted. In such cases the instruction is not completed, but may have been partially executed in the following respects.

- Some of the bytes of the storage operand may have been accessed, except that if access to a given byte of the storage operand would violate storage protection, that byte is neither copied to a register by a Load instruction nor modified by a Store instruction. Also, the rules for storage accesses given in Section 6.8.1, “Guarded Storage” and in Section of Book II are obeyed.

- Some registers may have been altered as described in the Book II section cited above.

- Reference and Change bits may have been updated as described in Section 6.7.12.

- For a \textit{stbcx.}, \textit{sthcx.}, \textit{stwcx.}, \textit{stdcx.}, or \textit{stqcx.} instruction that is executed in-order, CR0 may have been set to an undefined value and the reservation may have been cleared.

The architecture does not support continuation of an aborted instruction but intends that the aborted instruction be re-executed if appropriate.

---

### Programming Note

An exception may result in the partial execution of a \textit{Load} or \textit{Store} instruction. For example, if the Page Table Entry that translates the address of the storage operand is altered, by a program running on another thread, such that the new contents of the Page Table Entry preclude performing the access, the alteration could cause the \textit{Load} or \textit{Store} instruction to be aborted after having been partially executed.

As stated in the Book II section cited above, if an instruction is partially executed the contents of registers are preserved to the extent that the instruction can be re-executed correctly. The consequent preservation is described in the following list. For any given instruction, zero, one, or two items in the list apply.

- For a fixed-point \textit{Load} instruction that is not a multiple or string form, if RT=RA or RT=RB then the contents of register RT are not altered.
- For an \textit{lq} instruction, if RT+1 = RA then the contents of register RT+1 are not altered.
- For an update form \textit{Load} or \textit{Store} instruction, the contents of register RA are not altered.
7.7 Exception Ordering

Since multiple exceptions can exist at the same time and the architecture does not provide for reporting more than one interrupt at a time, the generation of more than one interrupt is prohibited. Some exceptions, such as the Mediated External exception, persist and can be deferred. However, other exceptions would be lost if they were not recognized and handled when they occur. For example, an External interrupt was generated when a Data Storage exception existed, the Data Storage exception would be lost. If the Data Storage exception was caused by a Store Multiple instruction for which the storage operand crosses a virtual page boundary and the exception was a result of attempting to access the second virtual page, the store could have modified locations in the first virtual page even though it appeared that the Store Multiple instruction was never executed.

For the above reasons, all exceptions are prioritized with respect to other exceptions that may exist at the same instant to prevent the loss of any exception that is not persistent. Some exceptions cannot exist at the same instant as some others.

Data Storage, Hypervisor Data Storage, Data Segment, and Alignment exceptions occur as if the storage operand were accessed one byte at a time in order of increasing effective address (with the obvious caveat if the operand includes both the maximum effective address and effective address 0). (The required ordering of exceptions on components of non-atomic accesses does not extend to the performing of the component accesses in the event of an exception. For example, if byte n causes a data storage exception, it is not necessarily true that the access to byte n-1 has been performed.)

7.7.1 Unordered Exceptions

With one exception, the exceptions listed here are unordered, meaning that they may occur at any time regardless of the state of the interrupt processing mechanism. These exceptions are recognized and processed when presented. The exception is that a Machine Check caused by an attempt to access an accelerator as other than an operand of copy or paste is ordered similarly to the corresponding type of storage access exception. (Note that this results in two different orderings. The one for instruction fetch occurs early, as item 2 in the "Instruction-Caused and Precise" list. The one for data access appears later, within case 3 of the appropriate "Function-Dependent" listings.)

1. System Reset
2. Machine Check except for those caused by an invalid attempt to access an accelerator

7.7.2 Ordered Exceptions

The exceptions listed here are ordered with respect to the state of the interrupt processing mechanism. With one exception, in the following list the hypervisor forms of the Data Storage and Instruction Storage exceptions can be substituted for the non-hypervisor forms since the hypervisor forms cannot be caused by the same instruction and have the same ordering. The exception is that Virtual Page Class Key Storage Protection exceptions that occur when LPCRKBV=1 and Virtualized Partition Memory is disabled by VPM=0 cause only a Hypervisor Data Storage exception (and never a Data Storage exception).

In the list below for Instruction-Caused and Precise exceptions, for prefixed instructions items 1, 2, and 6 apply to the first word of the instruction, and determination of whether the exceptions of items 3-5 and 7 occur is based on the first word of the instruction. (Items 3-7 can occur only for prefixed instructions.)

Programming Note

For a prefixed instruction there is no need to determine whether the exceptions of items 1, 2, and 6 can be caused by the second word of the instruction.

- If the instruction is correctly aligned (i.e., is at an effective address that is not equal to 60 modulo 64), the determination would be the same for the second word as for the first word.
- If the instruction is not correctly aligned, an exception will occur due to one of items 1-7 applied to the first word, and the corresponding interrupt obviates the need for hardware to access the second word.

System-Caused or Imprecise

1. Program
   - Imprecise Mode Floating-Point Enabled Exception
2. Directed Ultravisor Doorbell
3. Hypervisor Maintenance

Instruction-Caused and Precise

1. Instruction Segment
2. [Hypervisor] Instruction Storage other than case described in item 6
3. Hypervisor Emulation Assistance due to PCR making all prefixed instructions unavailable
4. Hypervisor Facility Unavailable due to HFSCR making all prefixed instructions unavailable
5. Facility Unavailable due to HFSCR making all prefixed instructions unavailable
6. [Hypervisor] Instruction Storage for prefixed instruction in Caching Inhibited storage
7. Alignment for incorrectly aligned prefixed instruction
For implementations that execute multiple instructions in parallel using pipeline or superscalar techniques, or combinations of these, it can be difficult to understand the ordering of exceptions. To understand this ordering it is useful to consider a model in which each instruction is fetched, then decoded, then executed, all before the next instruction is fetched. In this model, the exceptions a single instruction would generate are in the order shown in the list of instruction-caused exceptions. Exceptions with different numbers have different ordering. Exceptions with the same numbering but different lettering are mutually exclusive and cannot be caused by the same instruction. The Hypervisor Virtualization, External, [Hypervisor] Decrementer, Performance Monitor, Directed Privileged Doorbell, and Directed Hypervisor Doorbell interrupts have equal ordering. Similarly, where Data Storage, Data Segment, and Alignment exceptions are listed in the same item, and where Hypervisor Emulation Assistance and Privileged Instruction exceptions are listed in the same item, they have equal ordering.

Even on threads that are capable of executing several instructions simultaneously, or out of order, instruction-caused interrupts (precise and imprecise) occur in program order.

---

**Programming Note**

Despite that debug address matches are EA based, the exceptions they cause are not necessarily ordered before translation-caused exceptions. For example, it may be considered advantageous to take a page fault that would have prevented an access rather than a DAWR match exception.

---

### 7.8 Event-Based Branch Exception Ordering

Event-based exceptions are not ordered because they can occur simultaneously. Whenever an event-based exception occurs and the exception is enabled, the corresponding “exception occurred” bit in the BESCR is set to 1. See Section 6.2.1 of Book II.

### 7.9 Interrupt Priorities

This section describes the relationship of nonmaskable, maskable, precise, and imprecise interrupts. In the following descriptions, the interrupt mechanism waiting for all possible exceptions to be reported includes only exceptions caused by previously initiated instructions (e.g., it does not include waiting for the Decrementer to step through zero). The exceptions are listed in order of highest to lowest priority. The phrase “corresponding interrupt” means the interrupt
having the same name as the exception unless the thread is in power-saving mode, in which case the phrase means the System Reset interrupt.

Unless otherwise stated or obvious from context, it is assumed below that one of the following conditions is satisfied.

- The thread is not in power-saving mode and the interrupt, unless it is the Machine Check interrupt, is not disabled. (For the Machine Check interrupt no assumption is made regarding enablement.)
- The thread is in power-saving mode and the exception is enabled to cause exit from the mode.

With one exception, in the following list the hypervisor forms of the Data Storage and Instruction Storage exceptions can be substituted for the non-hypervisor forms since the hypervisor forms cannot be caused by the same instruction and have the same priority. The exception is that exceptions caused by Virtual Page Class Key Storage Protection exceptions that occur when LPCRKEYV=1 and Virtualized Partition Memory is disabled by VPM=0 cause only a Hypervisor Data Storage exception (and never a Data Storage exception).

1. System Reset

System Reset exception has the highest priority of all exceptions. If this exception exists, the interrupt mechanism ignores all other exceptions and generates a System Reset interrupt.

Once the System Reset interrupt is generated, no nonmaskable interrupts are generated due to exceptions caused by instructions issued prior to the generation of this interrupt.

2. Machine Check

With one exception, the Machine Check exception is the second highest priority exception. If this exception exists and a System Reset exception does not exist, the interrupt mechanism ignores all other exceptions and generates a Machine Check interrupt. The exception is that a Machine Check caused by an attempt to access an accelerator as other than an operand of copy or paste, is prioritized similarly to the corresponding type of storage access exception. (Note that this results in two different priorities. The one for data access is higher, appearing as item e or f in the listings for different types of Load and Store instructions. The one for instruction fetch is lower, in category K.)

Once the Machine Check interrupt is generated, no nonmaskable interrupts are generated due to exceptions caused by instructions issued prior to the generation of this interrupt.

3. Instruction-Caused and Precise

This exception is the third highest priority exception. When this exception is created, the interrupt mechanism waits for all possible Imprecise exceptions to be reported. It then generates the appropriate ordered interrupt if no higher priority exception exists when the interrupt is to be generated. Within this category a particular instruction may present more than a single exception. When this occurs, those exceptions are ordered in priority as indicated in the following lists. Where [Hypervisor] Data Storage, Data Segment, and Alignment exceptions are listed in the same item they have equal priority (i.e., the hardware may generate any one of the three interrupts for which an exception exists).

A. Fixed-Point Loads and Stores
   a. These exceptions are mutually exclusive and have the same priority:
      - Hypervisor Emulation Assistance
      - Program - Privileged Instruction
   b. Hypervisor Facility Unavailable
   c. Facility Unavailable
   d. Data Storage for the case of Fixed-Point Load or Store Caching Inhibited instructions with MSRDR=1 or the case of an invalid function code for an Atomic Memory Operation
   e. all other Data Storage, Hypervisor Data Storage, [Hypervisor] Data Segment, Machine Check for invalid accelerator access, or Alignment (other than for incorrectly aligned prefixed instruction)
   f. Trace

B. Floating-Point Loads and Stores
   a. Hypervisor Emulation Assistance
   b. Hypervisor Facility Unavailable
   c. Floating-Point Unavailable

H. rfebb, rfscv, rfid, hrfid, urfid, and mtmsr[d]
   a. These exceptions are mutually exclusive and have the same priority:
      - Program - Privileged Instruction, for all except rfebb
      - Hypervisor Emulation Assistance, for rfebb, rfscv, hrfid and mtmsr
   b. Hypervisor Facility Unavailable (rfebb only)
   c. Facility Unavailable (rfebb only)
   d. Program - Floating-Point Enabled Exception, for all except rfebb
   e. Trace, for rfebb and mtmsr[d] only

I. Other Instructions
   a. These exceptions or groups of exceptions are mutually exclusive and have the same priority (the members of a group are not mutually exclusive, but have the same priority):
      - Program - Trap
      - System Call
      - System Call Vectored
      - Hypervisor Emulation Assistance or Program (Privileged Instruction)
   b. Hypervisor Facility Unavailable
   c. Facility Unavailable
   d. Trace

J. [Hypervisor] Instruction Storage, Instruction Segment, Alignment for incorrectly aligned prefixed instruction, and Machine Check for invalid accelerator access

These exceptions have the lowest priority in this category. They are recognized only when all instructions prior to the instruction causing one of these exceptions appear to have completed and that instruction is the next instruction to be executed. The four exceptions are mutually exclusive.

The priority of these exceptions is specified for completeness and to ensure that they are not given more favorable treatment. It is acceptable for an implementation to treat these exceptions as though they had a lower priority.

4. Program - Imprecise Mode Floating-Point Enabled Exception

This exception is the fourth highest priority exception. When this exception is created, the interrupt mechanism waits for all other possible exceptions to be reported. It then generates this interrupt if no higher priority exception exists when the interrupt is to be generated.

5. Directed Ultravisor Doorbell

This exception is the fifth highest priority exception. When this exception is created, the interrupt mechanism waits for all other possible exceptions to be reported. It then generates this interrupt if no higher priority exception exists when the interrupt is to be generated.

6. Hypervisor Maintenance

This exception is the sixth highest priority exception. When this exception is created, the interrupt mechanism waits for all other possible exceptions to be reported. It then generates this interrupt if no higher priority exception exists when the interrupt is to be generated.

If a Hypervisor Maintenance exception exists and each attempt to execute an instruction when the Hypervisor Maintenance interrupt is enabled causes an exception (see the Programming Note below), the Hypervisor Maintenance interrupt is not delayed indefinitely.

These exceptions are the lowest priority exceptions. All have equal priority (i.e., the hardware may generate any one of the corresponding interrupts for which an exception exists). When one of

---

Programming Note

Some platform implementations may depend on timely servicing of Hypervisor Maintenance interrupts, e.g. to prevent physical damage. The Directed Ultravisor Doorbell interrupt handler may test the HMER to identify such circumstances and take appropriate action.
these exceptions is created, the interrupt processing mechanism waits for all other possible exceptions to be reported. It then generates the corresponding interrupt if no higher priority exception exists when the interrupt is to be generated.

If a Hypervisor Decrementer exception exists and each attempt to execute an instruction when the Hypervisor Decrementer interrupt is enabled causes an exception (see the Programming Note below), the Hypervisor Decrementer interrupt is not delayed indefinitely.

If LPES=0 and a Direct External exception exists and each attempt to execute an instruction when this interrupt is enabled causes an exception (see the Programming Note below), the Direct External interrupt is not delayed indefinitely.

7.10.3 EBB Classes
Event-based branches are classified by whether they are directly caused by the execution of an instruction or are caused by some other system exception. Those that are "system-caused" are
- Performance Monitor
- External

Programming Note
An incorrect or malicious operating system could corrupt the first instruction in the interrupt vector location for an instruction-caused interrupt such that the attempt to execute the instruction causes the same exception that caused the interrupt (a looping interrupt; e.g., Trap instruction and Program interrupt). Similarly, the first instruction of the interrupt vector for one instruction-caused interrupt could cause a different instruction-caused interrupt, and the first instruction of the interrupt vector for the second instruction-caused interrupt could cause the first instruction-caused interrupt (e.g., Program interrupt and Floating-Point Unavailable interrupt). The looping caused by these and similar cases is terminated by the occurrence of a System Reset or Hypervisor Decrementer interrupt.

7.10 Relationship of Event-Based Branches to Interrupts

7.10.1 EBB Exception Priority
Event-based branches have a priority lower than that of all interrupts. When an event-based exception is created, the Event-Based Branch facility waits for all possible exceptions that would cause interrupts to be reported. It then generates the event-based branch if no exception that would cause an interrupt exists when the event-based branch is to be generated.

7.10.2 EBB Synchronization
When an event-based branch occurs, EBBRR is set to point to an instruction such that all preceding instruc-
Chapter 8. Timer Facilities

8.1 Overview

The Time Base, Decrementer, Hypervisor Decrementer, Processor Utilization of Resources, and Scaled Processor Utilization of Resources registers provide timing functions for the system. The remainder of this section describes these registers and related facilities.

8.2 Time Base (TB)

The Time Base (TB) is a 64-bit register (see Figure 69) containing a 64-bit unsigned integer that is incremented periodically.

```
   0  39
TBU40 ///
   0  32  63
TBU TBL
```

<table>
<thead>
<tr>
<th>Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>TBU40</td>
<td>Upper 40 bits of Time Base</td>
</tr>
<tr>
<td>TBU</td>
<td>Upper 32 bits of Time Base</td>
</tr>
<tr>
<td>TBL</td>
<td>Lower 32 bits of Time Base</td>
</tr>
</tbody>
</table>

Figure 69. Time Base

The Time Base is a hypervisor resource; see Chapter 2.

The SPRs TBU40, TBU, and TBL provide access to the fields of the Time Base shown in Figure 69. When a `mtspr` instruction is executed specifying one of these SPRs, the associated field of the Time Base is altered and the remaining bits of the Time Base are not affected.

See Chapter 5 of Book II for information about the update frequency of the Time Base.

The Time Base is implemented such that:

1. Loading a GPR from the Time Base has no effect on the accuracy of the Time Base.

2. Copying the contents of a GPR to the Time Base replaces the contents of the Time Base with the contents of the GPR.

The Power ISA does not specify a relationship between the frequency at which the Time Base is updated and other frequencies, such as the CPU clock or bus clock in a Power ISA system. The Time Base update frequency is not required to be constant. What is required, so that system software can keep time of day and operate interval timers, is one of the following.

- The system provides an (implementation-dependent) interrupt to software whenever the update frequency of the Time Base changes, and a means to determine what the current update frequency is.
- The update frequency of the Time Base is under the control of the system software.

Implementations must provide a means for either preventing the Time Base from incrementing or preventing it from being read in problem state (MSR_PP=1). If the means is under software control, it must be accessible only in hypervisor state (MSR_HVP=0b10). There must be a method for getting all Time Bases in the system to start incrementing with values that are identical or almost identical.
8.2.1 Writing the Time Base

Writing the Time Base is privileged, and can be done only in hypervisor state. Reading the Time Base is not privileged; it is discussed in Chapter 5 of Book II.

It is not possible to write the entire 64-bit Time Base using a single instruction. The `mttbl` and `mttbu` extended mnemonics write the lower and upper halves of the Time Base (TBL and TBU), respectively, preserving the other half. These are extended mnemonics for the `mtspr` instruction; Figure 19.

The Time Base can be written by a sequence such as:

```assembly
lwz Rx,upper # load 64-bit value for
lwz Ry,lower # TB into Rx and Ry
li Rz,0
mttbl Rz # set TBL to 0
mttbu Rx # set TBU
mttbl Ry # set TBU
```

Provided that no interrupts occur while the last three instructions are being executed, loading 0 into TBL prevents the possibility of a carry from TBL to TBU while the Time Base is being initialized.

The preferred method of changing the Time Base utilizes the TBU40 facility. The following code sequence demonstrates the process. Assume the upper 40 bits of Rx contain the desired value upper 40 bits of the Time Base.

```assembly
mftb Ry # Read 64-bit Time Base value
clrldi Ry,Ry,40 # lower 24 bits of old TB
mttbu40 Rx # write upper 40 bits of TB
mftb Rz # read TB value again
cmpld Rz,Ry # compare new and old lwr 24
bge done # no carry out of low 24 bits
addis Rx,Rx,0x0100 #increment upper 40 bits
mttbu40 Rx # update to adjust for carry
```

Programming Note

If software initializes the Time Base on power-on to some reasonable value and the update frequency of the Time Base is constant, the Time Base can be used as a source of values that increase at a constant rate, such as for time stamps in trace entries.

Even if the update frequency is not constant, values read from the Time Base are monotonically increasing (except when the Time Base wraps from $2^{64}-1$ to 0). If a trace entry is recorded each time the update frequency changes, the sequence of Time Base values can be post-processed to become actual time values.

Successive readings of the Time Base may return identical values.

If Time Base bits 60:63 are used as part of a random number generator, software must account for the fact that these bits are set to 0x0 only when bit 59 changes state regardless of whether or not they incremented to 0xF since they were previously set to 0x0.

See the description of the Time Base in Chapter 5 of Book II for ways to compute time of day in POSIX format from the Time Base.

8.3 Virtual Time Base

The Virtual Time Base (VTB) is a 64-bit incrementing counter.

![Figure 70. Virtual Time Base](#)

VTB

0 63

Virtual Time Base increments at the same rate as the Time Base until its value becomes 0xFFFFFFFF_0000_0000 (2^{64} - 1); at the next increment its value becomes 0x0000_0000_0000_0000. There is no interrupt or other indication when this occurs.

The operation of the Virtual Time Base has the following additional properties.

1. Loading a GPR from the Virtual Time Base has no effect on the accuracy of the Virtual Time Base.

2. Copying the contents of a GPR to the Virtual Time Base replaces the contents of the Virtual Time Base with the contents of the GPR.

Programming Note

In systems that change the Time Base update frequency for purposes such as power management, the Virtual Time Base input frequency will also change. Software must be aware of this in order to set interval timers.
8.4 Decrementer

The Decrementer (DEC) is a decrementing counter that provides a mechanism for causing a Decrementer interrupt after a programmable delay.

The Decrementer is driven at the same frequency as the Time Base.

In configurations in which the hypervisor allows multiple partitions to time-share a processor, the Virtual Time Base can be managed by the hypervisor such that it appears to each partition as if it counts only during the times that the partition is executing.

In order to do this, the hypervisor saves the value of the Virtual Time Base as part of the program context when removing a partition from the processor, and restores it to its previous value when initiating the partition again on the same or another processor.

The LPCR is used to enable and disable Large Decrementer mode, as defined below. (See Section 2.2.)

When the Decrementer is not in Large Decrementer mode, it behaves as a 32-bit signed integer and operates as follows.

The Decrementer counts down until its value becomes 0x0000_0000_0000_0000; at the next decrement its value becomes 0x0000_0000_FFFF_FFFF. When reading the Decrementer using \texttt{mfspr}, bits 0:31 always read back as 0s.

When the contents of DEC\(_{32}\) change from 0 to 1, a Decrementer exception will come into existence within a reasonable period of time. When the contents of DEC\(_{32}\) change from 1 to 0, the existing Decrementer exception, if any, will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event.

The preceding paragraph applies regardless of whether the change in the contents of DEC\(_{32}\) is the result of decrementation of the Decrementer by the hardware or of modification of the Decrementer caused by execution of an \texttt{mtspr} instruction.

The Decrementer has the following additional properties.

1. Loading a GPR from the Decrementer has no effect on the accuracy of the Time Base.
2. Copying the contents of a GPR to the Decrementer replaces the contents of the Decrementer with the contents of the GPR.

When the Decrementer is in Large Decrementer mode, it behaves as a d-bit decrementing counter which is sign-extended to 64 bits. The value of d is implementation dependent but at least 32. When the Decrementer is written, bits 0:63-d are ignored by the hardware.

In Large Decrementer mode, the maximum positive value supported by the Decrementer is \(2^{d-1}-1\), represented with bits 0:64-d containing 0's and bits 65-d:63 containing 1's. The minimum value supported by the Decrementer is \(-2^{d-1}\), represented as 0xFFFF_FFFF_FFFF_FFFF.

When in Large Decrementer mode, the Decrementer operates as follows.

The binary value of the Decrementer counts down until its value becomes 0x0000_0000_0000_0000; at the next decrement its value becomes the minimum value supported, which is represented as 0xFFFF_FFFF_FFFF_FFFF.

The contents of the DEC\(_{0}\) change from 0 to 1, a Decrementer exception will come into existence within a reasonable period of time. When the contents of DEC\(_{0}\) change from 1 to 0, the existing Decrementer exception, if any, will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event.

The preceding paragraph applies regardless of whether the change in the contents of DEC\(_{0}\) is the result of decrementation of the Decrementer by the hardware or of modification of the Decrementer caused by execution of an \texttt{mtspr} instruction.

In systems that change the Time Base update frequency for purposes such as power management, the Decrementer input frequency will also change. Software must be aware of this in order to set interval timers.

If Decrementer bits 60:63 are used as part of a random number generator, software must account for the fact that these bits are set to 0xF only when bit 59 changes state regardless of whether or not they decremented to 0x0 since they were previously set to 0xF.
8.4.1 Writing and Reading the Decrementer

The contents of the Decrementer can be read or written using the `mfspr` and `mtspr` instructions, both of which are privileged when they refer to the Decrementer. Using an extended mnemonic (Figure 19), the Decrementer can be written from GPR Rx using:

```
mtdec Rx
```

The Decrementer can be read into GPR Rx using:

```
mfdec Rx
```

Copying the Decrementer to a GPR has no effect on the Decrementer contents or on the interrupt mechanism.

8.5 Hypervisor Decrementer

The Hypervisor Decrementer is a h-bit decrementing counter that is sign-extended to 64 bits. The value of h is implementation dependent, however the number of bits supported by the Hypervisor Decrementer must be greater than or equal to the number of bits supported by the Decrementer. When the Decrementer is written, bits 0:63-h are ignored by the hardware.

The binary value of the Hypervisor Decrementer counts down until its value becomes 0x0000_0000_0000_0000; at the next decrement its value becomes the minimum value supported, which is represented as 0xFFFF_FFFF_FFFF_FFFF.

When the contents of HDEC0 change from 0 to 1 and the thread is not in a power-saving mode, a Hypervisor Decrementer exception will come into existence within a reasonable period of time. When a Hypervisor Decrementer interrupt occurs, the existing Hypervisor Decrementer exception will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event. Even if multiple HDEC0 change transitions from 0 to 1 occur before a Hypervisor Decrementer interrupt occurs, at most one Hypervisor Decrementer exception exists.

The preceding paragraph applies regardless of whether the change in the contents of HDEC0 is the result of decrementation of the Hypervisor Decrementer by the hardware or of modification of the Hypervisor Decrementer caused by execution of an `mtspr` instruction.

The operation of the Hypervisor Decrementer has the following additional properties.

1. Loading a GPR from the Hypervisor Decrementer has no effect on the accuracy of the Hypervisor Decrementer.
2. Copying the contents of a GPR to the Hypervisor Decrementer replaces the contents of the Hypervisor Decrementer with the contents of the GPR.

### Programming Note

In systems that change the Time Base update frequency for purposes such as power management, the Hypervisor Decrementer update frequency will also change. Software must be aware of this in order to set interval timers.

If Hypervisor Decrementer bits 60:63 are used as part of a random number generator, software must account for the fact that these bits are set to 0xF only when bit 59 changes state regardless of whether or not they decremented to 0x0 since they were previously set to 0xF.

### Programming Note

A Hypervisor Decrementer exception is not created if the thread is in a power-saving mode when HDEC0 changes from 0 to 1 because having a Hypervisor Decrementer interrupt occur almost immediately after exiting the power-saving mode in this case is deemed unnecessary. The hypervisor already has control, and if a timed exit from the power-saving mode is necessary and possible, the hypervisor can use the Decrementer to exit the power-saving mode at the appropriate time. For some power-saving levels, the state of the Hypervisor Decrementer and Decrementer is not necessarily maintained and updated.

8.6 Processor Utilization of Resources Register (PURR)

The Processor Utilization of Resources Register (PURR) is a 64-bit counter, the contents of which provide an estimate of the resources used by the thread. The contents of the PURR are treated as a 64-bit unsigned integer.

```
<table>
<thead>
<tr>
<th>PURR</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
</tr>
</tbody>
</table>
```

**Figure 72. Processor Utilization of Resources Register**

The PURR is a hypervisor resource; see Chapter 2.
The contents of the PURR increase monotonically, unless altered by software, until the sum of the contents plus the amount by which it is to be increased exceed $0xFFFF_FFFF_FFFF_FFFF$ ($2^{64} - 1$) at which point the contents are replaced by that sum modulo $2^{64}$. There is no interrupt or other indication when this occurs.

The rate at which the value represented by the contents of the PURR increases is an estimate of the portion of resources used by the thread per unit time with respect to other threads that share those resources monitored by the PURR. When the thread is idle, the rate at which the PURR value increases is implementation dependent.

Let the difference between the value represented by the contents of the Time Base at times $T_a$ and $T_b$ be $T_{ab}$. Let the difference between the value represented by the contents of the PURR at time $T_a$ and $T_b$ be the value $P_{ab}$. The ratio of $P_{ab}/T_{ab}$ is an estimate of the percentage of shared resources used by the thread during the interval $T_{ab}$. For the set ($S$) of threads that share the resources monitored by the PURR, the sum of the usage estimates for all the threads in the set is 1.0.

The definition of the set of threads $S$, the shared resources corresponding to the set $S$, and specifics of the algorithm for incrementing the PURR are implementation-specific.

The PURR is implemented such that:

1. Loading a GPR from the PURR has no effect on the accuracy of the PURR.
2. Copying the contents of a GPR to the PURR replaces the contents of the PURR with the contents of the GPR.

### Programming Note

Estimates computed as described above may be useful for purposes related to resource utilization, including utilization-based system management and planning.

Because the rate at which the PURR accumulates resource usage estimates is dependent on the frequency at which the Time Base is incremented, and the frequency of the oscillator that drives instruction execution may vary independently from that of the Time Base, the interpretation of the contents of the PURR may be inaccurate as a measurement of capacity consumption for accounting purposes. The SPURR should be used for accounting purposes.

### 8.7 Scaled Processor Utilization of Resources Register (SPURR)

The Scaled Processor Utilization of Resources Register (SPURR) is a 64-bit counter, the contents of which provide an estimate of the resources used by the thread. The contents of the SPURR are treated as a 64-bit unsigned integer.

The SPURR is a hypervisor resource; see Section 2.6.

The contents of the SPURR increase monotonically, unless altered by software, until the sum of the contents plus the amount by which it is to be increased exceed $0xFFFF_FFFF_FFFF_FFFF$ ($2^{64} - 1$) at which point the contents are replaced by that sum modulo $2^{64}$. There is no interrupt or other indication when this occurs.

The rate at which the value represented by the contents of the SPURR increases is an estimate of the portion of resources used by the thread with respect to other threads that share those resources monitored by the SPURR, and relative to the computational capacity provided by those resources. The computational capacity provided by the shared resources may vary as a function of the frequency of the oscillator which drives the resources or as a result of deliberate delays in processing that are created to reduce power consumption. When the thread is idle, the rate at which the SPURR value increases is implementation dependent.

Let the difference between the value represented by the contents of the Time Base at times $T_a$ and $T_b$ be $T_{ab}$. Let the ratio of the effective and nominal frequencies of the oscillator driving instruction execution $f_e/f_n$ be $f_r$. Let the ratio of delay cycles created by power reduction circuitry and total cycles $c_d/c_t$ be $c_r$. Let the difference between the value represented by the contents of the SPURR at time $T_a$ and $T_b$ be the value $S_{ab}$. The ratio of $S_{ab}/(T_{ab} x f_r x (1 - c_r))$ is an estimate of the percentage of shared resource capacity used by the thread during the interval $T_{ab}$. For the set ($S$) of threads that share the resources monitored by the SPURR, the sum of the usage estimates for all the threads in the set is 1.0.

The definition of the set of threads $S$, the shared resources corresponding to the set $S$, and specifics of the algorithm for incrementing the SPURR are implementation-specific.

The SPURR is implemented such that:

1. Loading a GPR from the SPURR has no effect on the accuracy of the SPURR.
2. Copying the contents of a GPR to the SPURR replaces the contents of the SPURR with the contents of the GPR.

Programming Note
Estimates computed as described above may be useful for purposes of resource use accounting, program dispatching, etc.

8.8 Instruction Counter

The Instruction Counter (IC) is a 64-bit incrementing counter that counts the number of instructions that the thread has completed (according to the sequential execution model; see Section 2.2 of Book I).

Figure 74. Instruction Counter
Chapter 9. Debug Facilities

9.1 Overview

Implementations provide debug facilities to enable hardware and software debug functions, such as control flow tracing, data address watchpoints, and program single-stepping. The debug facilities described in this section consist of the Come-From Address Register (see Section 9.2), Completed Instruction Address Breakpoint Register (see Section 9.3), and the Data Address Watchpoint Register (DAWRn) and Data Address Watchpoint Register Extension (DAWRXn) (see Section 9.4). The interrupt associated with the Data Address Breakpoint registers is described in Section 7.5.3. The interrupt associated with the Completed Instruction Address Breakpoint Register is described in Section 7.5.15. The Trace facility, which can be used for single-stepping as well as for control flow tracing, is described in Section 7.5.15.

The \texttt{mfspr} and \texttt{mtspr} instructions (see Section 5.4.4) provide access to the registers of the debug facilities.

In addition to the facilities mentioned above, implementations typically provide debug facilities, modes, and access mechanisms that are implementation-specific. For example, implementations typically provide facilities for instruction address tracing, and also access to certain debug facilities via a dedicated interface such as the IEEE 1149.1 Test Access Port (JTAG).

9.2 Come-From Address Register

The Come-From Address Register (CFAR) is a 64-bit register. When an \texttt{rfebb}, \texttt{rfid}, or \texttt{rfscv} instruction is executed, the register is set to the effective address of the instruction. When a \texttt{Branch} instruction is executed and the branch is taken, the register is set to the effective address of an instruction in the instruction cache block containing the \texttt{Branch} instruction, except that if the \texttt{Branch} instruction is a B-form \texttt{Branch} (i.e., \texttt{bc}, \texttt{bca}, \texttt{bcl}, or \texttt{bcla}) for which the target address is in the instruction cache block containing the \texttt{Branch} instruction or is in the previous or next cache block, the register is not necessarily set. For \texttt{Branch} instructions, the setting need not occur until a subsequent context synchronizing operation has occurred.

![Figure 75. Come-From Address Register](image)

The contents of the CFAR can be read and written using the \texttt{mfspr} and \texttt{mtspr} instructions. Access to the CFAR is privileged.

--- Programming Note ---

This register can be used for purposes of debugging software. For example, often a software bug results in the program executing a portion of the code that it should not have reached or causing an unexpected interrupt. In the former case, a breakpoint can be placed in the portion of the code that was erroneously reached and the program reexecuted. In either case, the interrupt handler can save the contents of the CFAR (before executing the first instruction that would modify the register), and then make the saved contents available for a debugger to use in determining the control flow path by which the exception was reached.

In order to preserve the CFAR's contents for each partition and to prevent it from being used to implement a "covert channel" between partitions, the hypervisor should initialize/save/restore the CFAR when switching partitions on a given thread.

9.3 Completed Instruction Address Breakpoint

The Completed Instruction Address Breakpoint mechanism provides a means of detecting an instruction completion at a specific instruction address. The address comparison is done on an effective address (EA).

The Completed Instruction Address Breakpoint mechanism is controlled by the Completed Instruction Address Breakpoint Register (CIABR), shown in Figure 76, except that if SMFCTRLD=1 when PRIV≠0,
the Privilege specification in the PRIV field is ignored and the facility detects instruction address matches in ultravisor state.

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Name</th>

</tr>
<tr>
<td></td>
<td></td>
<td>11: Match in hypervisor non-ultravisor state</td>
</tr>
</tbody>
</table>

Figure 76. Completed Instruction Address Breakpoint Register

A Completed Instruction Address Breakpoint match occurs upon instruction completion if all of the following conditions are satisfied. The values of CIABR, SMFCTRL, and the MSR that are used for the comparisons are those that exist at the time the instruction is initiated.

- the completed instruction address is equal to CIEA_{0:61} \| 0b00. For prefixed instructions, the completed instruction address is the address of the prefix.
- SMFCTRLD=0 and the thread privilege matches that specified in PRIV or SMFCTRLD=1, PRIV ≠ 0, and MSR_{HV PR}=0b110.

In 32-bit mode the high-order 32 bits of the EA are treated as zeros for the purpose of detecting a match.

A Completed Instruction Address Breakpoint match causes a Trace exception, which may cause a Trace interrupt as described in Section 7.5.15.

9.4 Data Address Watchpoint

The Data Address Watchpoint mechanism provides a means of detecting load and store accesses to multiple doubleword-aligned effective address (EA) ranges. At least two independent address ranges are provided.

Programming Note

The Data Address Watchpoint mechanism employs a simple EA compare. It makes no attempt to take the radix table translation quadrants (keyed off EA_{0:1}) into account to enable a single setting to work in all privilege levels.

Each Data Address Watchpoint range is controlled by a pair of SPRs: the Data Address Watchpoint Register (DAWRn), shown in Figure 77, and the Data Address Watchpoint Register Extension (DAWRXn), shown in Figure 78, where n=0,1, ..., SMFCTRLD functions as an extension to the PRIVM field: when SMFCTRLD=1, the facility detects data address watchpoint matches in ultravisor state in addition to states enabled by the PRIVM field.

Figure 77. Completed Instruction Address Breakpoint Register

A Completed Instruction Address Breakpoint match occurs upon instruction completion if all of the following conditions are satisfied. The values of CIABR, SMFCTRL, and the MSR that are used for the comparisons are those that exist at the time the instruction is initiated.

- the completed instruction address is equal to CIEA_{0:61} \| 0b00. For prefixed instructions, the completed instruction address is the address of the prefix.
- SMFCTRLD=0 and the thread privilege matches that specified in PRIV or SMFCTRLD=1, PRIV ≠ 0, and MSR_{HV PR}=0b110.

In 32-bit mode the high-order 32 bits of the EA are treated as zeros for the purpose of detecting a match.

A Completed Instruction Address Breakpoint match causes a Trace exception, which may cause a Trace interrupt as described in Section 7.5.15.

9.4 Data Address Watchpoint

The Data Address Watchpoint mechanism provides a means of detecting load and store accesses to multiple doubleword-aligned effective address (EA) ranges. At least two independent address ranges are provided.

Programming Note

The Data Address Watchpoint mechanism employs a simple EA compare. It makes no attempt to take the radix table translation quadrants (keyed off EA_{0:1}) into account to enable a single setting to work in all privilege levels.

Each Data Address Watchpoint range is controlled by a pair of SPRs: the Data Address Watchpoint Register (DAWRn), shown in Figure 77, and the Data Address Watchpoint Register Extension (DAWRXn), shown in Figure 78, where n=0,1, ..., SMFCTRLD functions as an extension to the PRIVM field: when SMFCTRLD=1, the facility detects data address watchpoint matches in ultravisor state in addition to states enabled by the PRIVM field.

Figure 77. Data Address Watchpoint Register

Figure 78. Data Address Watchpoint Register Extension

The supported PRIVM values are 0b000, 0b001, 0b010, 0b011, 0b100, and 0b111 when SMFCTRLD=0 and 0b000, 0b001, 0b010, and 0b011 when SMFCTRLD=1. If the combination of SMFCTRLD and the PRIVM field does not contain one of the supported values, then whether a match occurs for a given storage access is undefined. Elsewhere in this section it is assumed that the PRIVM field contains one of the supported values.
When SMFCTRLD=0, PRIMV value 0b000 causes matches not to occur regardless of the contents of other DAWRx and DAWRxP fields. PRIMV values 0b101 and 0b110 are not supported because a storage location that is shared between the hypervisor and non-hypervisor software is unlikely to be accessed using the same EA by both the hypervisor and the non-hypervisor software. (PRIMV value 0b111 is supported primarily for reasons of software compatibility with respect to emulation of the DABR facility as described in a subsequent Programming Note.)

SMFCTRLD=1 is provided for ultravisor debugging and also for ultravisor supervision of secure partition debugging. When SMFCTRLD=1, exceptions due to matches that occur in hypervisor non-ultravisor state are unlikely to be desirable.

A Data Address Watchpoint match occurs for a Load or Store instruction, or for an instruction that is treated as a Load or Store, if, for any byte accessed, all of the following conditions are satisfied. For the first condition, chk_DEAW and chk_EA are defined as follows. If MSR[HV DB] = 0b10 and HRAMMC=1 then

chk_DEAW = 0b0 || DEAW1:60 and
chk_EA = 0b0 || EA1:63;

otherwise
chk_DEAW = DEAW and
chk_EA = EA.

The access is located in the range
chk_DEAW0:60 ≤ chk_EA0:60 ≤ (chk_DEAW0:60 + (550 || MRD0:5)) such that
(chk_EA0:60 AND (551 || 60)) = (chk_DEAW0:60 AND (551 || 60)).

(MSR[DR] = DAWRXnWT) | DAWRXnWT1

the thread is in
- ultravisor state and SMFCTRLD=1, or
- hypervisor non-ultravisor state and
DAWRXnhyp = 1, or
- privileged non-hypervisor state and
DAWRXnpnh = 1, or
- problem state and DAWRXnp = 1

the instruction is a Store or treated as a Store and
DAWRXnDW = 1, or the instruction is a Load or treated as a Load and DAWRXnDR = 1.

In hypervisor and ultravisor real addressing modes, bits 1:63-m of the EA are ignored for the purpose of detecting a match, where m is the real address size supported by the implementation. In virtual real addressing mode, the high order 24 bits of the EA are ignored for the purpose of detecting a match. In 32-bit mode the high-order 32 bits of the EA are treated as zeros for the purpose of detecting a match.

A watched range must not cross any of the following boundaries in their respective circumstances. If it does, the facility will operate correctly with respect to the various control parameters (e.g., PRIMV), but the set of EAs that cause matches is undefined.

- the 2^32-byte boundary when HPT translation is being performed in other than virtual real addressing mode (i.e., a range that includes the last and first byte of the 2^32-byte effective address space)
- a 2^32-byte boundary when the thread is in hypervisor or ultravisor real addressing mode (i.e., a range that, if the corresponding EAs were used to address storage on a design that ignores the high-order bits of the 60-bit real address that are not supported by the implementation, would include the last and first byte of the 2^32-byte effective address space)
- a 2^32-byte boundary when Radix Tree translation is being performed (i.e., a quadrant boundary)
- a 2^32-byte boundary when HPT translation is being performed in virtual real addressing mode (i.e., a range that, if the corresponding EAs were used to address storage, would include the last and first byte of the reserved virtual segment)
- a 2^32-byte boundary when the thread is in 32-bit mode (i.e., a range that, if the corresponding EAs were used to address storage, would include the last and first byte of the 2^32-byte effective address space)

If the above conditions are satisfied, it is undefined whether a match occurs in the following cases.

- The instruction is Store Conditional but the store is not performed
- The instruction is dcbz. (For the purpose of determining whether a match occurs, dcbz is treated as a Store.)

The Cache Management instructions other than dcbz never cause a match.

A Data Address Watchpoint match causes a Data Storage exception or a Hypervisor Data Storage exception (see Section 7.5.3, “Data Storage Interrupt (DSI)” on page 1266 and Section 7.5.16, “Hypervisor Data Storage Interrupt (HDSI)” on page 1277). If a match occurs, some or all of the bytes of the storage operand may have been accessed; however, if a Store instruction causes the match, the storage operand is not modified if the instruction is one of the following:

- any Store instruction that causes an atomic access

Programming Note

The Data Address Watchpoint mechanism does not apply to instruction fetches.
The limitations of the Data Address Watchpoint mechanism may lead to uncertainties when attempting to interpret a reported match. For example, there is no explicit indication of which watchpoint matched. The watched address ranges could overlap, for example, as a result of the doubleword granularity of the address range specification, making it unclear which watchpoint matched. Even if one of the overlapping watchpoints was set to match only for stores and the other only for loads, the existence of the Atomic Memory Operations would make the reporting of a store in the DSISR inconclusive. For a given watchpoint, the doubleword granularity may make the validity of the match uncertain because only the starting address of the match is reported without a length. In such cases, it is necessary to examine the operand that caused the match to determine what actually happened.

Implementations that comply with versions of the architecture that precede Version 2.02 do not provide the DABRX (now replaced by DAWRXn). Forward compatibility for software that was written for such implementations (and uses the Data Address Breakpoint facility) can be obtained by setting DAWRXn[60:63] to 0b0111.
Chapter 10. Performance Monitor Facility

10.1 Overview

The Performance Monitor facility provides a means of collecting information about program and system performance.

10.2 Performance Monitor Operation

The Performance Monitor facility includes the following features.

- an MSR bit
  - PMM (Performance Monitor Mark), which can be used to select one or more programs for monitoring

- registers
  - PMC1 - PMC6 (Performance Monitor Counters 1 - 6), which count events
  - MMCR0, MMCR1, MMCR2, MMCR3 and MMCRA (Monitor Mode Control Registers 0, 1, 2, 3 and A), which control the Performance Monitor facility
  - SIAR, SDAR, SIER, SIER2 and SIER3 (Sampled Instruction Address Register, Sampled Data Address Register, Sampled Instruction Event Register, Sampled Instruction Event Register 2 and Sampled Instruction Event Register 3), which contain the address of the “sampled instruction” and of the “sampled data,” and additional information about the “sampled instruction” (see Section 10.4.8 - Section 10.4.10)

- the Performance Monitor interrupt and Performance Monitor event-based branch, which can be caused by monitored conditions and events.

A “counter negative condition” exists when the value in a PMC is negative (i.e., when bit 0 of the PMC is 1). A “Time Base transition event” occurs when a selected bit of the Time Base changes from 0 to 1 (the bit is selected by a field in MMCR0). The term “condition or event” is used as an abbreviation for “counter negative condition or Time Base transition event”. A condition or event can be caused implicitly by the hardware (e.g., incrementing a PMC) or explicitly by software (mtspr).

A condition or event is enabled if the corresponding “Enable” bit (i.e., PMC1CE, PMCjCE, or TBEE) in MMCR0 is 1. The occurrence of an enabled condition or event can have side effects within the Performance Monitor, such as causing the PMCs to cease counting.

An enabled condition or event causes a Performance Monitor alert if Performance Monitor alerts are enabled by the corresponding “Enable” bit in MMCR0. Another cause of a Performance Monitor alert is the threshold event counter reaching its maximum value (see Section 10.4.3). A single Performance Monitor alert may reflect multiple enabled conditions and events.

When a Performance Monitor alert occurs, MMCROPMAC is set to 1 and the writing of BHRB entries, if in process, is suspended.

When the contents of MMCROPMAC change from 0 to 1, a Performance Monitor exception will come into existence within a reasonable period of time. When the contents of MMCROPMAC change from 1 to 0, the existing Performance Monitor exception, if any, will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event.

A Performance Monitor exception causes one of the following.

- If MSR_EE = 1, MMCRO_EBE = 0, and either HFSCR_PM=1 or the thread is in hypervisor state, an interrupt occurs.
- If MSR_PR = 1, MMCRO_EBE = 1, a Performance Monitor event-based exception occurs if

Many aspects of the operation of the Performance Monitor are summarized by the following hierarchy, which is described starting at the lowest level.
BESCR\textsubscript{PME}=1, provided that event-based exceptions are enabled by FSCRE\textsubscript{EBB} and HFSCRE\textsubscript{EBB}. When a Performance Monitor event-based exception occurs, an event-based branch is generated if BESCR\textsubscript{OE}=1.

**Programming Note**

The Performance Monitor can be effectively disabled (i.e., put into a state in which Performance Monitor SPRs are not altered and Performance Monitor exceptions do not occur) by setting MMCR0 to 0x0000_0000_8000_0000.

The Performance Monitor also controls when BHRB entries are written, the instruction filters that are used when writing BHRB entries, and the availability of the BHRB in problem state. It also controls whether Performance Monitor exceptions cause Performance Monitor event-based exceptions or Performance Monitor interrupts. See Section 10.4.4.

### 10.3 No-op Instructions

**Reserved for the Performance Monitor**

The following forms of the \texttt{and x,x,x} instruction are reserved for exclusive use by the Performance Monitor.

- \texttt{and x,x,x}, where x=0,1.

**Programming Note**

An example usage of a probe no-op by the Performance Monitor is to measure branch prediction effectiveness. In order to do this, one of probe no-ops is inserted in various sections of the code in which branch prediction efficiency is being studied. The Performance Monitor registers are then set up as follows.

**MMCRA:**

- ES=010 (only probe no-ops eligible for sampling)
- SM=00 (all eligible instructions)
- SE=1 (enable random sampling).

Other fields in MMCRA are set as desired.

**MMCRI:**

- PMC1SEL=E0 (count PMC1 on dispatch)
- PMC4SEL=E0 (count PMC4 on completion)

Other counters initialized as desired.

**MMCRC:**

- Initialize as desired.

**MMCR0:**

- FC is set to 0 to stop freezing the counters
- PMAE is set to 1 to enable PMU alerts.

Other fields in MMCR0 are set as desired.

Subsequently, when a PMU alert occurs, PMCs 1 and 4 can be read. The difference between the two counter values provides an indication of branch prediction effectiveness in the areas of the code in which the probe no-op was inserted.

### 10.4 Performance Monitor Facility Registers

The Performance Monitor registers count events, control the operation of the Performance Monitor, and provide associated information.

The elapsed time between the execution of an instruction and the time at which events due to that instruction have been reflected in Performance Monitor registers is not defined. No means are provided by which software can ensure that all events due to preceding instructions have been reflected in Performance Monitor registers. Similarly, if the events being monitored may be caused by operations that are performed out-of-order, no means are provided by which software can prevent such events due to subsequent instructions from being reflected in Performance Monitor registers. Thus the contents obtained by reading a Performance Monitor register may not be precise: it may fail to reflect some events due to instructions that precede the \texttt{mfspkr} and may reflect some events due to instructions that follow the \texttt{mfspkr}. This lack of precision applies regardless of whether the state of the thread is such that the register is subject to change by the hardware at the time the
**10.4.1 Performance Monitor SPR Numbers**

The Performance Monitor registers have two sets of SPR numbers, one set that is non-privileged and another set that is privileged.

For the purpose of explanation elsewhere in the architecture, the non-privileged registers are divided into two groups as defined below.

- **A**: The non-privileged read/write Performance Monitor registers (i.e., the PMCs, MMCR0, MMCR2, and MMCRA at SPR numbers 771-776, 779, 769, and 770, respectively).

- **B**: The non-privileged read-only Performance Monitor registers (i.e., SIER2, SIER3, MMCR3, SIER, SIAR, SDAR, and MMCR1 at SPR numbers 736, 737, 738, 768, 780, 781, and 782, respectively).

The SPRs in group B are treated as undefined registers for write (mtspr) operations. See the mtspr instruction description in Section 5.4.4 for additional information.

When the PCR makes a register in either group A or B unavailable in problem state, that SPR is not included in group A or B.

**Programming Note**

Older versions of Performance Monitor facilities used different sets of SPR numbers from those shown in Section 5.4.4. (All 32-bit PowerPC implementations used a different set.)

**10.4.2 Performance Monitor Counters**

The six Performance Monitor Counters, PMC1 through PMC6, are 32-bit registers that count events.

**Programming Note**

Depending on the events being monitored, the contents of Performance Monitor registers may be affected by aspects of the runtime environment (e.g., cache contents) that are not directly attributable to the programs being monitored.

**Programming Note**

PMC5 and PMC6 are defined to facilitate calculating basic performance metrics such as cycles per instruction (CPI).

**Programming Note**

Software can use a PMC to "pace" the collection of Performance Monitor data. For example, if it is desired to collect event counts every n cycles, software can specify that a particular PMC count cycles, and set that PMC to 0x8000_0000 - n. The events of interest would be counted in other PMCs. The counter negative condition that will occur after n cycles can, with the appropriate setting of MMCR bits, cause counter values to become frozen, cause a Performance Monitor exception to occur, etc.

**10.4.2.1 Event Counting and Sampling**

The PMCs are enabled to count unless they are “frozen” by one or more of the “freeze counters” fields in MMCR0 or MMCR2.

Each of PMC’s 1-4 can be configured, using MMCR1, to count “continuous” events (events that can occur at any time), or to count “randomly sampled” events (or “sampled” events) that are associated with the execution of randomly sampled instructions.
Continuous events always cause the counters to count (unless counters are frozen). These events are specified for each counter by using encodes F0-FF in the PMCn Selector fields in MMCRI.

Randomly sampled events can cause the counters to count only when random sampling has been enabled by setting MMCRA[SE]=1. The types of instructions that are sampled are specified in MMCRA[SM] and MMCRA[ES]. Randomly sampled events are specified for each counter by using encodes E0-EF in the PMCn Selector fields in MMCRI.

**Programming Note**

A typical sequence of operations that enables use the PMCs is as follows.

- Freeze the counters by setting MMCR0[FC]=1.
- Set control fields in MMCR0 and MMCR2 that control counting in various privilege states and other modes, and that enable counter negative conditions.
- Initialize the events to be counted by PMCs 1-4 using the PMCn Selector fields in MMCRI.
- Specify the BHRB filtering mode, threshold event Counter events, and whether or not random sampling is enabled in the corresponding fields in MMCRA.
- Initialize the PMCs to the values desired. For example, in order to configure a counter to cause a counter negative condition after n counts, that counter would be initialized to $2^{32-n}$.
- Set MMCR0[FC] to 0 to disable freezing the counters, and set MMCR0[PMAE] to 1 if a Performance Monitor alert (and the corresponding Performance Monitor interrupt) is desired when an enabled condition or event occurs. (See Section 10.2 for the definition of enabled condition or event.)

When the Performance Monitor alert occurs, the program would typically read the values of the counters as well as the contents of SIAR, SDAR, SIER as needed in order to extract the information that was being monitored.

See Sections 10.4.4 - 10.4.10 for information regarding MMCRs, SIAR, SDAR, and SIER, and some additional usage examples.

### 10.4.3 Threshold Event Counter

The threshold event counter and associated controls are in MMCRA (see Section 10.4.7). When Performance Monitor alerts are enabled (MMCR0[PMAE]=1), this counter begins incrementing from value 0 upon each occurrence of the event specified in the Threshold Event Counter Event (TECE) field after the event specified by the Threshold Start Event (TS) field occurs. The counter stops incrementing when the event specified in the Threshold End Event (TE) field occurs. The counter subsequently freezes until the event specified in the TS field is again recognized, at which point it restarts incrementing from value 0 as explained above. If the counter reaches its maximum value or a Performance Monitor alert occurs, incrementing stops. After the Performance Monitor alert occurs, the contents of the threshold event counter are not altered by the hardware until software sets MMCR0[PMAE] to 1.

**Programming Note**

Because hardware can modify the contents of the threshold event counter when random sampling is enabled (MMCRA[SE]=1) and MMCR0[PMAE]=1 at any time, any value written to the threshold event counter under this condition may be immediately overwritten by hardware.

The threshold event counter value is represented as a 3-bit integral power of 4, multiplied by a 7-bit integer. The exponent is contained in MMCRATECX, and the multiplier is contained in MMCRA[TECM]. For a given counter exponent, e, and multiplier, m, the number represented is as follows:

$$ N = 4^e \times m $$

This counter format allows the counter to represent a range of 0 through approximately 2 million counts with many fewer bits than would be required by a binary counter.

To represent a given counter value, hardware uses as e the smallest 3-bit integer for which a 7-bit integer exists such that the given counter value can be expressed using this format.

**Programming Note**

Software can obtain the number N from the contents of the threshold event counter by shifting the multiplier left twice times the value contained in the exponent.

The value in the counter is the exact number of events that occur for values from 0 through the maximum multiplier value (127), with 4 events of the exact value for values from 128 - 508 (or 127×4), within 16 events of the exact value for values from 512 - 2032 (or 127×4²), and so on. This represents an event count accuracy of approximately 3%, which is expected to be sufficient for most situations in which a count of events between a start and end event is required.
10.4.4 Monitor Mode Control Register 0

Monitor Mode Control Register 0 (MMCR0) is a 64-bit register as shown below.

<table>
<thead>
<tr>
<th>MMCR0</th>
<th>0</th>
<th>31</th>
</tr>
</thead>
</table>

Figure 80. Monitor Mode Control Register 0

MMCR0 is used to control multiple functions of the Performance Monitor. Some fields of MMCR0 are altered by the hardware when various events occur.

The following notation is used in the definitions below. “PMCs” refers to PMCs 1 - n and “PMCj” refers to PMCj, where 2 ≤ j ≤ n. n=4 when MMCR0PMCC=0b11 and n=6 otherwise.

When MMCR0PMCC is set to 0b10 or 0b11, providing problem state programs read/write access to MMCR0, only FC, PMAE, PMAO can be accessed. All other bits are not changed when mtspr is executed in problem state, and all other bits return 0s when mfspr is executed in problem state.

Programming Note

When using the threshold event counter, software typically specifies a “threshold counter exceeded n” event in MMCR1. This enables a PMC to count the number of times the counter exceeded a specified threshold value during the time Performance Monitor alerts were enabled.

The bit definitions of MMCR0 are as follows.

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:31</td>
<td>Reserved</td>
<td>0:31</td>
</tr>
<tr>
<td>32</td>
<td>Freeze Counters (FC)</td>
<td>0: The PMCs are incremented (if permitted by other MMCR bits). 1: The PMCs are not incremented.</td>
</tr>
<tr>
<td></td>
<td>The hardware sets this bit to 1 when an enabled condition or event occurs and MMCR0FCECE=1.</td>
<td></td>
</tr>
</tbody>
</table>

Programming Note

In order to freeze counters in problem state regardless of MSRHV, MMCR0FCPC must be set to 0 and MMCR0FCP must be set to 1.

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>33</td>
<td>Freeze Counters in Privileged State (FCS)</td>
<td>0: The PMCs are incremented (if permitted by other MMCR bits). 1: The PMCs are not incremented if MSRHVPR=0b00.</td>
</tr>
<tr>
<td></td>
<td>Conditionally Freeze Counters and BHRB in Problem State (FCP)</td>
<td>If the value of bit 51 (FCPC) is 0, this field has the following meaning. 0: The PMCs are incremented (if permitted by other MMCR bits) and entries are written into the BHRB (if permitted by the BHRB Instruction Filtering Mode field in MMCR0). 1: The PMCs are not incremented, and entries are not written into the BHRB, if MSRPR=1.</td>
</tr>
<tr>
<td>34</td>
<td>If the value of bit 51 (FCPC) is 1, this field has the following meaning. 0: The PMCs are not incremented, and entries are not written into the BHRB, if MSRHVPR=0b01. 1: The PMCs are not incremented, and entries are not written into the BHRB, if MSRHVPR=0b11.</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>35</td>
<td>Freeze Counters while Mark = 1 (FCM1)</td>
<td>0: The PMCs are incremented (if permitted by other MMCR bits). 1: The PMCs are not incremented if MSRPM=1.</td>
</tr>
<tr>

<td>Freeze Counters while Mark = 0 (FCM0)</td>
<td>0: The PMCs are incremented (if permitted by other MMCR bits). 1: The PMCs are not incremented if MSRPM=0.</td>
</tr>
</tbody>
</table>
| 36     | Performance Monitor Alert Enable (PMAE) | 0: Performance Monitor alerts are disabled and BHRB entries are not written. 1: Performance Monitor alerts are enabled, and BHRB entries are written (if enabled by other bits) until a Performance Monitor alert occurs, at which time:  
- MMCR0PMAE is set to 0  
- MMCR0PMAO is set to 1  
| 37     | | |
Freeze Counters on Enabled Condition or Event (FCECE)

0 The PMCs are incremented (if permitted by other MMCR bits).
1 The PMCs are incremented (if permitted by other MMCR bits) until an enabled condition or event occurs when MMCR0_INSTANCE=0, at which time:
   - MMCR0_FC is set to 1

If the enabled condition or event occurs when MMCR0_INSTANCE=1, the FCECE bit is treated as if it were 0.

Time Base Selector (TBSEL)

This field selects the Time Base bit that can cause a Time Base transition event (the event occurs when the selected bit changes from 0 to 1).

00 Time Base bit 47 is selected.
01 Time Base bit 51 is selected.
10 Time Base bit 55 is selected.
11 Time Base bit 63 is selected.

Time Base Event Enable (TBEE)

0 Time Base transition events are disabled.
1 Time Base transition events are enabled.

BHRB Available (BHRBA)

This field controls whether the BHRB instructions are available in problem state. If an attempt is made to execute a BHRB instruction in problem state when the BHRB instructions are not available, a Facility Unavailable interrupt will occur.

0 clrbhrb and mfbhrbe are not available in problem state.
1 clrbhrb and mfbhrbe are available in problem state unless they have been made unavailable by some other register.

Performance Monitor Event-Based Branch Enable (EBE)

This field controls whether Performance Monitor event-based branches and Performance Monitor event-based exceptions are enabled.

When Performance Monitor event-based branches and exceptions are disabled, no Performance Monitor event-based branches or exceptions occur regardless of the state of BESCR_PME.
0  Performance Monitor event-based branches and exceptions are disabled.
1  Performance Monitor event-based branches and exceptions are enabled.

**Programming Note**

In order to enable a problem state application to use the event-based Branch facility for Performance Monitor events, privileged software initializes MMCR1 to specify the events to be counted, and sets MMCR2, and MMCRA to specify additional sampling controls. MMCR0 should be initialized with PMCC set to 0b10 or 0b11 (to give problem state access to various Performance Monitor registers), PMAE and PMAO set to 0s (disabling Performance Monitor alerts), and EBE set to 1 (enabling Performance Monitor event-based branches and exceptions to occur). If the Event-Based Branch facility has not been enabled in the FSCR and HFSCR, it must be enabled in these registers as well.

The above operations by the operating system enable the application to control Performance Monitor event-based branching by means of BESCRPME (to enable or disable Performance Monitor event-based branching) and MMCR0PMAE (to enable or disable Performance Monitor alerts).

**PMC Control (PMCC)**

This field controls whether or not PMCs 5 - 6 are included in the Performance Monitor, and the accessibility of groups A and B (see Section 10.4.1) of non-privileged SPRs in problem state as described below.

00 PMCs 5 - 6 are included in the Performance Monitor. Group A is read-only, and group B read access behavior is conditional on MMCR0PMCEXT in problem state. If an attempt is made to write to an SPR in group A in problem state, a Hypervisor Emulation Assistance interrupt will occur.

01 PMCs 5 - 6 are included in the Performance Monitor. Group A is not allowed to be read or written in problem state, and group B is not allowed to be read in problem state. If an attempt is made, in problem state, to read or write to an SPR in group A, or to read from an SPR in group B, a Facility Unavailable interrupt will occur.

10 PMCs 5 - 6 are included in the Performance Monitor. Group A is allowed to be read and written in problem state, and group B except for MMCR1 (SPR 782) is allowed to be read in problem state. If an attempt is made to read MMCR1 in problem state, a Facility Unavailable interrupt will occur.

11 PMCs 5 - 6 are not included in the Performance Monitor. See Section 10.4.2 for details.

**Programming Note**

When the PCR makes SPRs unavailable in problem state, they are treated as undefined, and they are not included in groups A or B regardless of the value of PMCC. Thus when the PCR indicates a version of the architecture prior to V. 2.07 (i.e., PCRv2.06=1), the PMCC field does not affect SPRs MMCR2 or SIER, which are newly-defined in V. 2.07; these SPRs are treated as undefined registers. Accesses to them in problem state result in Hypervisor Emulation Assistance interrupts regardless of the value of PMCC, and Facility Unavailable interrupts do not occur for them. See Section 2.5 for additional information.
been made unavailable by the HFSCR (see Section 7.2.13).

**Programming Note**

In order to give problem state programs the same level of access to the Performance Monitor registers as was specified in Power ISA V 2.06, PMCC must be set to 0b00 (restricting access to read-only) and the PCR should indicate Version 2.06 (restricting access to the set of Performance Monitor SPRs and SPR bits that were defined in V 2.06).

When PMCC=0b00 and a write operation to a Performance Monitor register in group A or B is attempted in problem state, a Hypervisor Emulation Assistance interrupt occurs in order to maintain compatibility with V 2.06. For other values of PMCC, write or read operations to group A and read operations from group B that are not allowed result in Facility Unavailable interrupts. Facility Unavailable interrupts provide the operating system with more information about the type of disallowed access that was attempted than the Hypervisor Emulation Assistance interrupt provides. See Section 7.2.12 for additional information.

**Programming Note**

In order to prevent applications from accessing Performance Monitor registers, PMCC is set to 0b01.

In order to allow applications limited control over the Performance Monitor, PMCC is set to 0b10 or 0b11. These values are also used when Performance Monitor event-based branches are enabled.

**PMC1 Condition Enable** (PMC1CE)

This bit controls whether counter negative conditions due to a negative value in PMC1 are enabled.

0 Counter negative conditions for PMC1 are disabled.

1 Counter negative conditions for PMC1 are enabled.

### 49

**PMCj Condition Enable** (PMCjCE)

This bit controls whether counter negative conditions due to a negative value in any PMCj (i.e., in any PMC except PMC1) are enabled.

0 Counter negative conditions for all PMCjs are disabled.

1 Counter negative conditions for all PMCjs are enabled.

**Trigger** (TRIGGER)

0 The PMCs are incremented (if permitted by other MMCR bits).

1 PMC1 is incremented (if permitted by other MMCR bits). The PMCjs are not incremented until PMC1 is negative or an enabled condition or event occurs, at which time:

- the PMCjs resume incrementing (if permitted by other MMCR bits)
- MMCR0TRIGGER is set to 0

See the description of the FCECE bit, above, regarding the interaction between TRIGGER and FCECE.

**Programming Note**

Uses of TRIGGER include the following.

- Resume counting in the PMCjs when PMC1 becomes negative, without causing a Performance Monitor interrupt. Then freeze all PMCs (and optionally cause a Performance Monitor interrupt) when a PMCj becomes negative. The PMCjs then reflect the events that occurred between the time PMC1 became negative and the time a PMCj becomes negative. This use requires the following MMCR0 bit settings.
  - TRIGGER=1
  - PMC1CE=0
  - PMCjCE=1
  - TBEE=0
  - FCECE=1
  - PMAE=1 (if a Performance Monitor interrupt is desired)

- Resume counting in the PMCjs when PMC1 becomes negative, and cause a Performance Monitor interrupt without freezing any PMCs. The PMCjs then reflect the events that occurred between the time PMC1 became negative and the time the interrupt handler reads them. This use requires the following MMCR0 bit settings.
  - TRIGGER=1
  - PMC1CE=1
  - TBEE=0
  - FCECE=0
  - PMAE=1
Freeze Counters and BHRB in Problem State Condition (FCPC)

This bit controls the meaning of bit 34 (FCP). See the definition of bit 34 for details.

Programming Note
In order to enable the FCP bit to freeze counters in problem state regardless of MSR_HV, MMCR0_FCPC must be set to 0.

Freeze Counters, sampling and threshold counting in Ultravisor State (FCU)

0 The PMCs are incremented (if permitted by other MMCR bits).
1 The PMCs are not incremented, if MSR_SHV PR=0b110.

PMCC Extended (PMCCEXT)

0 If MMCR0_PMCC = b00, a SPR in group B is allowed to be read in problem state.
1 If MMCR0_PMCC = b00 and an attempt is made to read from an SPR in group B, a Facility Unavailable Interrupt will occur.

Control Counters 5 - 6 with Run Latch (CC5-6RUN)

When MMCR0_PMCC = b11, the setting of this bit has no effect; otherwise it is defined as follows.

0 PMCs 5 and 6 are incremented if CTRL_RUN=1 (if permitted by other MMCR bits).
1 PMCs 5 and 6 are incremented regardless of the value of CTRL_RUN (if permitted by other MMCR bits).

Performance Monitor Alert Occurred (PMAO)

0 A Performance Monitor alert has not occurred since the last time software set this bit to 0.
1 A Performance Monitor alert has occurred since the last time software set this bit to 0.

This bit is set to 1 by the hardware when a Performance Monitor alert occurs. This bit can be set to 0 only by the mtspr instruction.

Programming Note
Software can set this bit to 1 and set PMAE to 0 to simulate the occurrence of a Performance Monitor alert.
Software should set this bit to 0 after handling the Performance Monitor alert.

Freeze Counters 1-4 (FC1-4)

0 PMC1 - PMC4 are incremented (if permitted by other MMCR bits).
1 PMC1 - PMC4 are not incremented.

Freeze Counters 5-6 (FC5-6)

0 PMC5 - PMC6 are incremented (if permitted by other MMCR bits).
1 PMC5 - PMC6 are not incremented.

Freeze Counters 1-4 in Wait State (FC1-4WAIT)

0 PMCs 1-4 are incremented (if permitted by other MMCR bits).
1 PMCs 1-4, except for PMCs counting events that are not controlled by this bit, are not incremented if CTRL_RUN=0.

Programming Note
When PMC 1 is counting cycles, it is not controlled by this bit. See the description of the F0 event in Section 10.4.5.

Freeze Counters in Hypervisor State (FCH)

0 The PMCs are incremented (if permitted by other MMCR bits).
1 The PMCs are not incremented if MSR_SHV PR=0b010.

10.4.5 Monitor Mode Control Register 1

Monitor Mode Control Register 1 (MMCR1) is a 64-bit register as shown below.

Figure 81. Monitor Mode Control Register 1

MMCR1

0

63

MMCR1 enables software to specify the events that are counted by the PMCs.

In the following descriptions, events due to randomly sampled instructions occur only if random sampling is enabled (MMCRASE=1); all other events occur whenever the event specification is met regardless of the value of MMCRASE.

Various events defined below refer to “threshold A” through “threshold H”. The table below specifies the number of threshold event counter events corresponding to each of these thresholds.
The bit definitions of MMCR1 are as follows. Implementation-dependent MMCR1 bits that are not supported are treated as reserved.

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:31</td>
<td>Problem state access (SPR 782)</td>
</tr>
<tr>
<td></td>
<td>Privileged access (SPR 782 or 798)</td>
</tr>
<tr>
<td></td>
<td>Implementation-dependent</td>
</tr>
<tr>
<td>32:39</td>
<td><strong>PMC1 Selector</strong> (PMC1SEL)</td>
</tr>
<tr>
<td></td>
<td>The value of PMC1SEL specifies the event to be counted by PMC1 as defined below. All values in the range of E0 - FF that are not specified below are reserved.</td>
</tr>
<tr>
<td>Hex</td>
<td>Event</td>
</tr>
<tr>
<td>00</td>
<td>Disable events. (No events occur.)</td>
</tr>
<tr>
<td>01-BF</td>
<td>Implementation-dependent</td>
</tr>
<tr>
<td>C0-DF</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

The following events can occur only when random sampling is enabled (MMCRA_{SE}=1). The sampling modes corresponding to each event are listed in parentheses. (The sampling mode is specified in MMCRA_{SM}.)

- **E0** The thread has dispatched a randomly sampled instruction. (RIS)
- **E2** The thread has completed a randomly sampled Branch instruction for which the branch was taken. (RIS, RBS)
- **E4** The thread has failed to locate a randomly sampled instruction in the primary instruction cache. (RIS)
- **E6** The threshold event counter has exceeded the number of events corresponding to threshold A (see Table 6). (RIS, RLS, RBS)
- **E8** The threshold event counter has exceeded the number of events corresponding to threshold E (see Table 6). (RIS, RLS, RBS)

**Table 6: Event Counts for Thresholds A-H**

<table>
<thead>
<tr>
<th>Threshold</th>
<th>Events</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>4096</td>

</tr>
<tr>
<td>G</td>
<td>1024</td>
</tr>
<tr>
<td>H</td>
<td>2048</td>
</tr>
</tbody>
</table>

**PMC2 Selector** (PMC2SEL)

The value of PMC2SEL specifies the event to be counted by PMC2 as defined below. All values in the range of E0 - FF that are not specified below are reserved.

<table>
<thead>
<tr>
<th>Hex</th>
<th>Event</th>
</tr>
</thead>
<tbody>
<tr>
<td>00</td>
<td>Disable events. (No events occur.)</td>
</tr>
<tr>
<td>01-BF</td>
<td>Implementation-dependent</td>
</tr>
<tr>
<td>C0-DF</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

The following events can occur only when random sampling is enabled (MMCRA_{SE}=1). The sampling modes corresponding to each event are listed in parentheses. (The sampling mode is specified in MMCRA_{SM}.)

- **E0** The thread has obtained the data for a randomly sampled Load instruction from storage that did not reside in any cache. (RIS, RLS)
- **E2** The thread has failed to locate the data for a randomly sampled Load instruction in the primary data cache. (RIS, RLS)
E4 The thread filled a block in the primary data cache with data that were accessed by a randomly sampled Load instruction and obtained from a location other than the secondary or tertiary cache. (RIS, RLS)

E6 The threshold event counter has exceeded the number of events corresponding to threshold B (see Table 6). (RIS, RLS, RBS)

E6 The threshold event counter has exceeded the number of events corresponding to threshold F (see Table 6). (RIS, RLS, RBS)

The following events can occur regardless of whether random sampling is enabled.

F0 The thread has completed a Store instruction to the point at which it has reported all the exceptions it will cause.

F2 The thread has dispatched an instruction.

F4 A cycle has occurred during which the RUN bit of the thread’s CTRL register contained 1.

F6 The thread has failed to locate an ERAT entry during data address translation, and a new ERAT entry corresponding to the data effective address has been written.

F8 An external interrupt for the thread has occurred.

FA The thread has loaded an instruction from a higher level cache than the tertiary cache.

FE The thread has filled a block in the primary data cache with data that were accessed by a Load instruction and obtained from a location other than the secondary or tertiary cache.

**PMC3Selector (PMC3SEL)**

The value of PMC3SEL specifies the event to be counted by PMC3 as defined below. All values in the range of E0 - FF that are not specified below are reserved.

<table>
<thead>
<tr>
<th>Hex</th>
<th>Event</th>
</tr>
</thead>
<tbody>
<tr>
<td>00</td>
<td>Disable events. (No events occur.)</td>
</tr>
<tr>
<td>01-BF</td>
<td>Implementation-dependent</td>
</tr>
<tr>
<td>C0-DF</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

The following events can occur only when random sampling is enabled (MMCRA_SE=1). The sampling modes corresponding to each event are listed in parentheses. (The sampling mode is specified in MMCRA_SM.)

E2 The thread has completed a randomly sampled Store instruction to the point at which it has reported all exceptions it will cause. (RIS,RLS)

**PMC4 Selector (PMC4SEL)**

The value of PMC4SEL specifies the event to be counted by PMC4 as defined below. All values in the range of E0 - FF that are not specified below are reserved.

<table>
<thead>
<tr>
<th>Hex</th>
<th>Event</th>
</tr>
</thead>
<tbody>
<tr>
<td>00</td>
<td>Disable events. (No events occur.)</td>
</tr>
<tr>
<td>01-BF</td>
<td>Implementation-dependent</td>
</tr>
<tr>
<td>C0-DF</td>
<td>Reserved</td>
</tr>
</tbody>
</table>
are listed in parentheses. (The sampling mode is specified in MMMRASM.)

E0 The thread has completed a randomly sampled instruction. (RIS, RLS, RBS)
E4 The thread was unable to translate a data virtual address using the TLB for a randomly sampled instruction. (RIS, RLS)
E6 The thread has loaded a randomly sampled instruction from a higher level cache than the tertiary cache. (RIS)
E8 The thread has filled a block in the primary data cache with data that were accessed by a randomly sampled Load instruction and obtained from a location other than the secondary cache. (RIS, RLS)
EA The threshold event counter has exceeded the number of events corresponding to threshold D (see Table 6). (RIS, RLS, RBS)
EC The threshold event counter has exceeded the number of events corresponding to threshold H (see Table 6). (RIS, RLS, RBS)

The following events can occur regardless of whether random sampling is enabled.

F0 The thread has attempted to load data from the primary data cache but no block corresponding to the real address existed.
F2 A cycle has occurred during which the thread has dispatched one or more instructions.
F4 A cycle has occurred during which the PURR was incremented when the RUN bit of the thread’s CTRL register contained 1.
F6 The thread has mispredicted either whether or not the branch would be taken, or if taken, the target address of a Branch instruction.
F8 The thread has discarded prefetched instructions.
FA The thread has completed an instruction when the RUN bit of the thread’s CTRL register contained 1.
FC The thread was unable to translate an instruction virtual address using the TLB, and a new TLB entry corresponding to the instruction virtual address has been written.
FE The thread has obtained the data for a Load instruction from storage that did not reside in any cache.

--- Compatibility Note ---

In versions of the architecture that precede Version 2.02 the PMC Selector Fields were six bits long, and were split between MMMR0 and MMMR1. PMC1-8 were all programmable.

If more programmable PMCs are implemented in the future, additional MMMRs may be defined to cover the additional selectors.

10.4.6 Monitor Mode Control Register 2

Monitor Mode Control Register 2 (MMMR2) is a 64-bit register that contains 9-bit control fields for controlling the operation of PMC1 - PMC6 as shown below.

<table>
<thead>
<tr>
<th>C1</th>
<th>C2</th>
<th>C3</th>
<th>C4</th>
<th>C5</th>
<th>C6</th>
<th>Res’d</th>
</tr>

<td>0</td>
<td>8</td>
<td>9</td>
<td>17</td>
<td>18</td>
<td>26</td>
<td>27</td>
</tr>
<tr>
<td>35</td>
<td>36</td>
<td>44</td>
<td>45</td>
<td>53</td>
<td>54</td>
<td>63</td>
</tr>
</tbody>
</table>

Figure 82. Monitor Mode Control Register 2

When MMMR0PMCC = 0b11, fields C1 - C4 control the operation of PMC1 - PMC4, respectively and fields C5 and C6 are ignored by the hardware; otherwise, fields C1 - C6 control the operation of PMC1 - PMC6, respectively. The bit definitions of each Cn field are as follows, where n = 1, ..., 6.

When MMMR0PMCC is set to 0b10 or 0b11, providing problem state programs read/write access to MMMR2, only the FCnP0 bits can be accessed. All other bits are not changed when mtspr is executed in problem state, and all other bits return 0s when mfspr is executed in problem state.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Freeze Counter n in Privileged State (FCnP)</td>
</tr>
<tr>
<td>0</td>
<td>PMCn is incremented (if permitted by other MMMR bits).</td>
</tr>
<tr>
<td>1</td>
<td>PMCn is not incremented if MSRHV_PR=0b00.</td>
</tr>
<tr>
<td>1</td>
<td>Freeze Counter n in Problem State if MSRHV=0 (FCnP)</td>
</tr>
<tr>
<td>0</td>
<td>PMCn is incremented (if permitted by other MMMR bits).</td>
</tr>
<tr>
<td>1</td>
<td>PMCn is not incremented if MSRHV_PR=0b01.</td>
</tr>
</tbody>
</table>
Freeze Counter n in Problem State if MSRHV=1 (FCnP1)

0 PMCn is incremented (if permitted by other MMCR bits).
1 PMCn is not incremented if MSRHV PR=0b11.

Freeze Counter n while Mark = 1 (FCnM1)

0 PMCn is incremented (if permitted by other MMCR bits).
1 PMCn is not incremented if MSRPM=1.

Freeze Counter n while Mark = 0 (FCnM0)

0 PMCn is incremented (if permitted by other MMCR bits).
1 PMCn is not incremented if MSRRV PMM=0.

Freeze Counter n in Wait State (FCnWAIT)

0 PMCn is incremented (if permitted by other MMCR bits).
1 PMCn is not incremented if CTRL RUN=0.

Freeze Counter n in Hypervisor State (FCnH)

0 PMCn is incremented (if permitted by other MMCR bits).
1 PMCn is not incremented if MSRRV PR=0b10.

Bits 54:63 of MMCR2 are reserved.

10.4.7 Monitor Mode Control Register A

Monitor Mode Control Register A (MMCRA) is a 64-bit register as shown below.

| MMCRA | 0 | 63 |

The operating system is expected to set CTRL RUN to 0 when the thread is in a "wait state", i.e., when there is no process ready to run.

MMCRA gives privileged programs the ability to control the sampling process, BHRB filtering, and threshold events.

When MMCR0PMCC is set to 0b10 or 0b11, providing problem state programs read/write access to MMCRA, the Threshold Event Counter Exponent (TECX) and Threshold Event Counter Multiplier (TECM) fields are read-only, and all other fields return 0s, when mfspr is executed in problem state; all fields are not changed when mtspr is executed in problem state.

Programming Note

Problem state programs need access to this field in order to enable them to individually enable counters when analyzing sections of code. All the other fields will typically be initialized by the operating system.

Programming Note

Read/write access is provided to MMCRA in problem state (SPR 770) when MMCR0PMCC = 0b10 or 0b11 even though no fields can be modified by mtfspr because future versions of the architecture may allow various fields of MMCRA to be modified in problem state.

The bit definitions of MMCRA are as follows.

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:25</td>
<td>Problem state access (SPR 770) Reserved</td>
</tr>
<tr>
<td></td>
<td>Privileged access (SPR 770 or 786) Implementation-dependent</td>
</tr>
<tr>
<td>26</td>
<td>BHRB Recording Disable (BHRBRD)</td>
</tr>
<tr>
<td></td>
<td>This field controls whether BHRB entries are written when BHRB recording is enabled by other bits.</td>
</tr>
<tr>
<td>27:31</td>
<td>Problem state access (SPR 770) Reserved</td>
</tr>
<tr>
<td></td>
<td>Privileged access (SPR 770 or 786) Implementation-dependent</td>
</tr>
<tr>
<td>32:33</td>
<td>BHRB Instruction Filtering Mode (IFM)</td>
</tr>
<tr>
<td></td>
<td>This field controls the filter criterion used by the hardware when recording Branch instructions into the BHRB. See Section 10.5.</td>
</tr>
<tr>
<td>00</td>
<td>All taken Branch instructions are entered into the BHRB unless prevented by other filtering fields.</td>
</tr>
<tr>
<td>01</td>
<td>Only taken calls are entered into the BHRB. Includes direct and indirect: bl, bla, bcl, bcla, bcctl, bcctr, bctar.</td>
</tr>
<tr>
<td>10</td>
<td>Only taken indirect branches (excluding calls) are entered into BHRB: bcrl, bcctr, bctar. This translates to all XL-form taken branches with LK=0.</td>
</tr>
<tr>
<td>11</td>
<td>Only taken conditional branches: bc, bca, bcl, bcla, bclr, bclrl, bcctr, bcctrl, bctar, bctar.</td>
</tr>
</tbody>
</table>
bctarl. This translates to all B-form or XL-form taken branches except those with the BO field encoded to branch always (BO=0b1z1zz).

**Programming Note**

Filtering mode 10 provides additional filtering for unconditional Branch instructions, and for indirect Branch instructions only the target address is recorded.

Filtering mode 11 provides additional filtering for instructions that provide a hint or for which the outcome does not depend on the value of the Condition Register.

### 34:36

**Threshold Event Counter Exponent (TECX)**

This field species the exponent of the threshold event counter value. See Section 10.4.3 for additional information. The maximum exponent supported is at least 5.

### 37

Reserved

### 38:44

**Threshold Event Counter Multiplier (TECM)**

This field species the multiplier of the threshold event counter value. See Section 10.4.3 for additional information.

**Programming Note**

When MMCRO\textsubscript{PMCC} = 0b10 or 0b11, providing problem-state programs read-write access to MMCRA, problem state programs are able to read only the TECX and TECM fields (and are not able to write any fields). The values of these fields are needed during the processing of an event-based branch that occurs due to a counter negative condition for a PMC that was counting “threshold counter exceeded n” events (e.g. MMCRI\textsubscript{PMC1SEL} = 0xE8). Reading these fields enables the application to determine the amount by which the threshold was exceeded. Applications are not given access to other fields, and these other fields must initialized by the operating system.

### 45:47

**Threshold Event Counter Event (TECE)**

This field specifies the event, if any, that is counted by the threshold event counter. The values and meanings are follows.

<table>
<thead>
<tr>
<th>Value</th>
<th>Event</th>
</tr>
</thead>
<tbody>
<tr>
<td>000</td>
<td>Disable counting.</td>
</tr>
<tr>
<td>001</td>
<td>A cycle has occurred.</td>
</tr>
<tr>
<td>010</td>
<td>An instruction has completed.</td>
</tr>
<tr>
<td>011</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

All other values are implementation-dependent.

**Threshold Start Event (TS)**

This field specifies the event that causes the threshold event counter to start counting occurrences of the event specified in the Threshold Event Counter Event (TECE) field. The events only occur if MMCRA\textsubscript{SE}=1 (random sampling enabled) and one of the sampling modes listed in parenthesis is in effect. (The sampling mode that is currently in effect is specified in MMCRA\textsubscript{SM}.)

0000 Reserved

0001 The thread has randomly sampled an instruction while it is being decoded. (RIS)

0010 The thread has dispatched a randomly sampled instruction. (RIS)

0011 A randomly sampled instruction has been sent to a facility (e.g. Branch, Fixed Point, etc.) (RIS, RLS, RBS)

0100 The thread has completed a randomly sampled instruction to the point at which it has reported all exceptions it will cause. (RIS, RLS, RBS)

0101 The thread has completed a randomly sampled instruction. (RIS, RLS, RBS)

0110 The thread has failed to locate data for a randomly sampled Load instruction in the primary data cache. (RIS, RLS)

0111 The thread has filled a block in the primary data cache with data that were accessed by a randomly sampled Load instruction. (RIS, RLS)

The definition of the following values depends on whether the access to MMCRA is in problem state or in privileged state.

Problem state access (SPR 770)

1000 - 1111 - Reserved

Privileged access (SPR 770 or 786)

1000 - 1111 - Implementation-dependent

**Threshold End Event (TE)**

This field specifies the event that causes the threshold event counter to stop counting occurrences of the event specified in the Threshold Event Counter Event (TECE) field. The events only occur if MMCRA\textsubscript{SE}=1 (random sampling enabled) and one of the sampling modes listed in parenthesis is in effect. (The sampling mode that is currently in effect is specified in MMCRA\textsubscript{SM}.)

0000 Reserved

0001 The thread has randomly sampled an instruction while it is being decoded. (RIS)
0010 The thread has dispatched a randomly sampled instruction. (RIS)
0011 A randomly sampled instruction has been sent to a facility (e.g. Branch, Fixed Point, etc.) (RIS, RLS, RBS)
0100 The thread has completed a randomly sampled instruction to the point at which it has reported all exceptions that it will cause. (RIS, RLS, RBS)
0101 The thread has completed a randomly sampled instruction. (RIS, RLS, RBS)
0110 The thread has failed to locate data for a randomly sampled Load instruction in the primary data cache. (RIS, RLS)
0111 The thread has filled a block in the primary data cache with data that were accessed by a randomly sampled Load instruction. (RIS, RLS)

The definition of the following values depends on whether the access to MMCRA is in problem state or in privileged state.

Problem state access (SPR 770)
1000 - 1111 - Reserved
Privileged access (SPR 770 or 786)
1000 - 1111 - Implementation-dependent

56 Reserved

57:59 Eligibility for Random Sampling (ES)
When random sampling is enabled (MMCRA$_{SE}$=1) and the SM field indicates random instruction sampling (RIS), the encodings of this field specify the instructions that are eligible to be sampled as follows.
000 All instructions
001 All Load and Store instructions
010 All probe no-op instructions
011 Reserved

The definition of the following values depends on whether the access to MMCRA is in problem state or in privileged state.

Problem state access (SPR 770)
100 - 111 - Reserved
Privileged access (SPR 770 or 786)
100 - 111 - Implementation-dependent

60 Reserved

61:62 Random Sampling Mode (SM)
00 Random Instruction Sampling (RIS) - Instructions that meet the criterion specified in the ES field for random instruction sampling are eligible to be sampled.
01 Random Load/Store Facility Sampling (RLS) - Instructions that meet the criterion specified in the ES field for random Load/Store Facility sampling are eligible for sampling.
10 Random Branch Facility Sampling (RBS) - Instructions that meet the criterion specified in the ES field for random Branch Facility sampling are eligible for sampling.
11 Reserved
**Random Sampling Enable (SE)**

0  Random sampling is disabled.
1  Random sampling is enabled.

See Section 10.4.2.1 for information about random sampling.

### 10.4.8 Sampled Instruction Address Register

The Sampled Instruction Address Register (SIAR) is a 64-bit register.

<table>
<thead>
<tr>
<th>SIAR</th>
<th>//</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>63</td>
</tr>
<tr>
<td>62</td>
<td></td>
</tr>
</tbody>
</table>

**Figure 84. Sampled Instruction Address Register**

When a Performance Monitor alert occurs because of an event caused by execution of a randomly sampled instruction, bits 0:61 of the SIAR contain bits 0:61 of the effective address of the instruction if $\text{SIERSIARV} = 1$ and contains an undefined value if $\text{SIERSIARV} = 0$.

When a Performance Monitor alert occurs because of an event other than an event caused by execution of a randomly sampled instruction, the SIAR contains the effective address of an instruction that was being executed, possibly out-of-order, at or around the time that the Performance Monitor alert occurred.

The instruction located at the effective address contained in the SIAR is called the “sampled instruction”.

Except as described in the next paragraph, the contents of SIAR may be altered by the hardware if and only if $\text{MMCR0PMAE=1}$. Thus after the Performance Monitor alert occurs, the contents of SIAR are not altered by the hardware until software sets $\text{MMCR0PMAE}$ to 1. After software sets $\text{MMCR0PMAE}$ to 1, the contents of SIAR are undefined until the next Performance Monitor alert occurs.

If single step or branch tracing is active ($\text{MSRTE = 0b10}$ or $\text{0b01}$), the contents of SIAR as used by the Performance Monitor facility are undefined and may change even when $\text{MMCR0PMAE=0}$.

**Programming Note**

When the Performance Monitor alert occurs, $\text{SIER_{AMPPR \, SAMPHV}}$ indicates the value of $\text{MSRHV PR}$ that was in effect when the sampled instruction was being executed. (The contents of these SIER bits are visible only in privileged state.)

### 10.4.9 Sampled Data Address Register

The Sampled Data Address Register (SDAR) is a 64-bit register.

<table>
<thead>
<tr>
<th>SDAR</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
</tr>
<tr>
<td>63</td>
</tr>
</tbody>
</table>

**Figure 85. Sampled Data Address Register**

When a Performance Monitor alert occurs because of an event caused by execution of a randomly sampled instruction, the SDAR contains the effective address of the storage operand of the instruction if $\text{SIERSDARV} = 1$ and contains an undefined value if $\text{SIERSDARV} = 0$.

When a Performance Monitor alert occurs because of an event other than an event caused by execution of a randomly sampled instruction, the SDAR contains the effective address of the storage operand of an instruction that was being executed, possibly out-of-order, at or around the time that the Performance Monitor alert occurred. This storage operand may or may not be the storage operand (if any) of the sampled instruction.

The data located at the effective address contained in the SDAR are called the “sampled data.”

Except as described in the next paragraph, the contents of SDAR may be altered by the hardware if and only if $\text{MMCR0PMAE=1}$. Thus after the Performance Monitor alert occurs, the contents of SDAR are not altered by the hardware until software sets $\text{MMCR0PMAE}$ to 1. After software sets $\text{MMCR0PMAE}$ to 1, the contents of SDAR are undefined until the next Performance Monitor alert occurs.

If single step or branch tracing is active ($\text{MSRTE = 0b10}$ or $\text{0b01}$), the contents of SDAR as used by the Performance Monitor facility are undefined and may change even when $\text{MMCR0PMAE=0}$.

### 10.4.10 Sampled Instruction Event Register

The Sampled Instruction Event Register (SIER) is a 64-bit register.

<table>
<thead>
<tr>
<th>SIER</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
</tr>
<tr>
<td>63</td>
</tr>
</tbody>
</table>

**Figure 86. Sampled Instruction Event Register**

When random sampling is enabled and a Performance Monitor alert occurs because of an event caused by execution of a randomly sampled instruction, the SIER contains information about the sampled instruction. The contents of all fields are valid unless otherwise indicated.
When random sampling is disabled or when a Performance Monitor alert occurs because of an event that was not caused by execution of a randomly sampled instruction, the contents of the SIER are undefined.

The contents of SIER may be altered by the hardware if and only if MMCR0.PMAE=1. Thus after the Performance Monitor alert occurs, the contents of SIER are not altered by the hardware until software sets MMCR0.PMAE to 1. After software sets MMCR0.PMAE to 1, the contents of SIER are undefined until the next Performance Monitor alert occurs.

The bit definitions of the SIER are as follows.

0:37 The definition of these bits depends on whether the access to SIER is in problem state or in privileged state.

Problem state access (SPR 768)
Reserved
Privileged access (SPR 768 or 784)
Implementation-dependent

38:40 The definition of these bits depends on whether the access to SIER is in problem state or in privileged state.

Problem state access (SPR 768)
Reserved
Privileged access (SPR 768 or 784)

38 Sampled MSRPR (SAMPPR)
Value of MSRPR when the Performance Monitor alert occurred.

39 Sampled MSRHV (SAMPHV)
Value of MSRHV when the Performance Monitor alert occurred.

40 Reserved

41 SIAR Valid (SIARV)
Set to 1 when the contents of the SIAR are valid (i.e., they contain the effective address of the sampled instruction); otherwise set to 0.

42 SDAR Valid (SDARV)
Set to 1 when the contents of the SDAR are valid (i.e., they contain the effective address of the sampled instruction); otherwise set to 0.

43 Threshold Exceeded (TE)
Set to 1 by the hardware if the contents of the threshold event counter exceeded the maximum value when the Performance Monitor alert occurred; otherwise set to 0 by the hardware.

44 Slew Down
Set to 1 by the hardware if the processor clock was lower than nominal when the Performance Monitor alert occurred; otherwise set to 0 by the hardware.

45 Slew Up
Set to 1 by the hardware if the processor clock was higher than nominal when the Performance Monitor alert occurred; otherwise set to 0 by the hardware.

46:48 Sampled Instruction Type (SITYPE)
This field indicates the sampled instruction type. The values and their meanings are as follows.

000 The hardware is unable to indicate the sampled instruction type
001 Load Instruction
010 Store instruction
011 Branch Instruction
100 Floating-Point Instruction other than a Load or Store instruction
101 Fixed-Point Instruction other than a Load or Store instruction
110 Condition Register or System Call instruction
111 Reserved

49:51 Sampled Instruction Cache Information (SICACHE)
This field provides cache-related information about the sampled instruction.

000 The hardware is unable to provide any cache-related information for the sampled instruction.
001 The thread obtained the instruction in the primary instruction cache.
010 The thread obtained the instruction in the secondary cache.
011 The thread obtained the instruction in the tertiary cache.
100 The thread failed to obtain the instruction in the primary, secondary, or tertiary cache
101 Reserved
110 Reserved
111 Reserved

52 Sampled Instruction Taken Branch (SITAKBR)
Set to 1 if the SITYPE field indicates a Branch instruction and the branch was taken; otherwise set to 0.

53 Sampled Instruction Mispredicted Branch (SIMISPRED)
Set to 1 if the SITYPE field indicates a Branch instruction and the thread has mispredicted either whether or not the branch would be taken, or if taken, the target address; otherwise set to 0.

54:55  **Sampled Branch Instruction Misprediction Information** (SIMISPREDI)

If SIMISPRED=1, this field indicates how the thread mispredicted the outcome of a Branch instruction; otherwise this field is set to 0s.

00  The instruction was not a mispredicted Branch instruction.
01  The thread mispredicted whether or not the branch would be taken because the contents of the Condition Register differed from the predicted contents.
10  The thread mispredicted the target address of the instruction.
11  Reserved

56  **Sampled Instruction Data ERAT Miss (SIDERAT)**

When the SITYPE field indicates a Load or Store instruction, this field is set to 1 if the thread has failed to locate an ERAT entry during data address translation for the sampled instruction and otherwise is set to 0.

When the SITYPE field does not indicate a Load or Store instruction, the contents of this field are undefined.

57:59  **Sampled Instruction Data Address Translation Information** (SIDAXLATE)

This field contains information about data address translation for the sampled instruction. If multiple data address translations were performed, the information pertains to the last translation. The values and their meanings are as follows.

000  The instruction did not require data address translation.
001  The thread translated the data virtual address using the TLB.
010  A PTEG required for data address translation for the instruction was obtained from the secondary cache.
011  A PTEG required for data address translation for the instruction was obtained from the tertiary cache.
100  A PTEG required for data address translation for the instruction was obtained from storage that did not reside in any cache.
101  A PTEG required for data address translation for the instruction was obtained from a cache on a different multi-threaded processor that resides on the same chip as the thread.
110  A PTEG required for data address translation for the instruction was obtained from a cache on a different chip from the thread.
111  Reserved

60:62  **Sampled Instruction Data Storage Access Information** (SIDSATI)

This field contains information about data storage accesses made by the sampled instruction. The values and their meanings are as follows.

000  The instruction did not require data address translation.
001  The instruction was a Read for which the thread obtained the referenced data from the primary data cache.
010  The instruction was a Read for which the thread obtained the referenced data from the secondary cache.
011  The instruction was a Read for which the thread obtained the referenced data from the tertiary cache.
100  The instruction was a Read for which the thread obtained the referenced data from storage that did not reside in any cache.
101  The instruction was a Read for which the thread obtained the referenced data from a cache on a different multi-threaded processor that resides on the same chip as the thread.
110  The instruction was a Read for which the thread obtained the referenced data from a cache on a different chip from the thread.
111  The instruction was a Store for which the data were placed into a location other than the primary data cache.

63  **Sampled Instruction Completed** (SICMPL)

Set to 1 if the sampled instruction has completed; otherwise set to 0.

10.4.11 Other Performance Monitor Registers

SIER2, SIER3 and MMCR3 are 64-bit registers. The contents of these registers are implementation-dependent.
The Branch History Rolling Buffer (BHRB) is described in Chapter 7 of Book II but only at the level required by application programmers. Additional aspects of the BHRB are described here.

In order to enable problem state programs to use the BHRB, MMCR0BHRBA must be set to 1 to enable execution of clrbhrb and mfbhrbe instructions in problem state. Additionally, MMCR0PMCC must be set to 0b10 or 0b11 to allow problem state programs to read and write the necessary Performance Monitor registers. (See Section 10.4.4.)

If Performance Monitor event-based branching is desired, MMCR0EBE must also be set to 1 to enable Performance Monitor event-based branches.

### Programming Note

Applications are expected to access the contents of SIER2, SIER3 and MMCR3 by means of a privileged service program which will be typically invoked by a system call and which is capable of interpreting the contents of these registers, and returns to the application a generalized summary of the register contents in a form that is not implementation-dependent.

The recommended secure configuration of the Performance Monitor Facility is to disable access to group B Performance Monitor registers in problem state via setting MMCR0PMCC and MMCR0PMCC\_CEXT appropriately, which is congruous to the programming model described above.

### 10.5 Branch History Rolling Buffer

The Branch History Rolling Buffer (BHRB) is described in Chapter 7 of Book II but only at the level required by application programmers. Additional aspects of the BHRB are described here.

In order to enable problem state programs to use the BHRB, MMCR0BHRBA must be set to 1 to enable execution of clrbhrb and mfbhrbe instructions in problem state. Additionally, MMCR0PMCC must be set to 0b10 or 0b11 to allow problem state programs to read and write the necessary Performance Monitor registers. (See Section 10.4.4.)

If Performance Monitor event-based branching is desired, MMCR0EBE must also be set to 1 to enable Performance Monitor event-based branches.

### 10.5.1 BHRB Filtering

When the BHRB is written by hardware, only those Branch instructions that meet the filtering criterion specified in MMCRA\_IFM and for which the branch was taken are included.

Filtering restricts the type of Branch instructions that are entered into the BHRB. The filtering criteria are defined using the following terminology.

- **Call**: A Branch instruction with the LK field set to 1.
- **Return**: A \texttt{bclr} instruction with the BH field set to 0s.
- **Jump**: Any Branch instruction that is not a call or a return.
- **Conditional Branch**: Any Branch instruction other than an I-Form Branch instruction, or a B- or XL-Form Branch instruction with the BO field set to “branch always.” (See Figure 40 in Book I.)
- **Unconditional Branch**: Any Branch instruction other than a conditional branch instruction
- **Indirect Branch**: Any XL-Form Branch instruction
- **Direct Branch**: Any B- or I-Form Branch instruction

Software is able to prevent various combinations of each of the above types of Branch instructions from being entered into the BHRB using the IFM field in MMCRA. (See Section 10.4.7, “Monitor Mode Control Register A”.)

The BHRB is written by the hardware only in problem state (MSR\_PR=1), and if and only if MMCR0PMAC=1 and MMCRABHRBRD=0. After MMCR0PMAC has been set to 1 and a Performance Monitor alert occurs, MMCR0PMAC is set to 0 and the BHRB is not altered by hardware until software sets MMCR0PMAC to 1 again.

When MMCR0PMAC=1, \texttt{mfbhbrbe} instructions return 0s to the target register.

### Programming Note

\texttt{mfbhbrbe} instructions return 0s when MMCR0PMAE=1 in order to prevent software from reading the BHRB while it is being written by hardware.
Chapter 11. Processor Control

11.1 Overview

The Processor Control facility provides a mechanism for the ultravisor or hypervisor to send messages to other threads in the system. Privileged non-hypervisor programs are able to send messages to other threads on the same multi-threaded processor; however if the processor is configured into sub-processors, privileged non-hypervisor programs can only send messages to other threads on the same sub-processor.

11.2 Programming Model

Ultravisor-level, hypervisor-level, and privileged-level messages can be sent. Ultravisor-level messages are sent using the `msgsndu` instruction and cause ultravisor-level exceptions when received. Hypervisor-level messages are sent using the `msgsnd` instruction and cause hypervisor-level exceptions when received. Privileged-level messages are sent using the `msgsndp` instruction and cause privileged-level exceptions when received. For all three instructions, the message type and destination threads are specified in a General Purpose Register.

If a message is received by a thread, the exception corresponding to the message type is generated. When the exception is generated, the corresponding interrupt occurs when no higher priority exception exists and the interrupt is enabled (MSR\textsubscript{EE}=1 for the Directed Privileged Doorbell interrupt, MSR\textsubscript{EE}=1 or MSR\textsubscript{HV}=0 for the Directed Hypervisor Doorbell interrupt, and MSR\textsubscript{EE}=1 or MSR\textsubscript{3 HV PR}=0b110 for the Directed Ultravisor Doorbell interrupt).

A Directed Privileged Doorbell exception remains until the corresponding interrupt occurs, or the exception is cleared by execution of a `mtspr(DPDES)` or `msgclrp` instruction.

A Directed Hypervisor Doorbell exception remains until the corresponding interrupt occurs, or the exception is cleared by execution of a `msgclrp` instruction.

A Directed Ultravisor Doorbell exception remains until the corresponding interrupt occurs, or the exception is cleared by execution of a `msgclru` instruction.

If a Doorbell exception of a given privilege is present and the corresponding interrupt is pended because MSR\textsubscript{EE}=0, additional Doorbell exceptions of that privilege are ignored until the exception is cleared.

11.3 Processor Control Registers

11.3.1 Directed Privileged Doorbell Exception State

The layout of the Directed Privileged Doorbell Exception State (DPDES) register is shown in Figure 87.

![Figure 87. Directed Privileged Doorbell Exception State Register](image)

The DPDES register is a 64-bit register. For \( t < T \), where \( T \) is the number of threads on the sub-processor (or on the multi-threaded processor if sub-processors are not supported), bit 63-\( t \) corresponds to the thread with privileged thread number \( t \).

The value of bit \( t \) indicates the presence of a Directed Privileged Doorbell exception on the thread with privileged thread number \( t \). Bit \( t \) is cleared when a Directed Privileged Doorbell interrupt occurs on thread \( t \).

When the contents of DPDES\( _{63-t} \) change from 0 to 1, a Directed Privileged Doorbell exception will come into existence on privileged thread number \( t \) within a reasonable period of time. When the contents of DPDES\( _{63-t} \) change from 1 to 0, the existing Directed Privileged Doorbell exception, if any, on privileged thread number \( t \), will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event on privileged thread number \( t \).

The preceding paragraph applies regardless of whether the change in the contents of DPDES\( _{63-t} \) is the result a `msgsndp` or `msgclrp` instruction or of modification of the DPDES register caused by execution of an `mtspr` (DPDES) instruction.

Bits 0:63-\( T \) of the DPDES are reserved.
The primary use of the DPDES is to provide the means for the hypervisor to save a [sub-]processor's Directed Privileged Doorbell exception state when the set of programs running on the [sub-]processor is swapped out or moved from one [sub-]processor to another. Since there is no such need for a similar function for the hypervisor or ultravisor, there is no similar register for the hypervisor or ultravisor. Privileged programs are able to read the DPDES in order to poll for Directed Privileged Doorbell exceptions when the corresponding interrupt is disabled (MSR$_{EE}$=1).
11.4 Processor Control Instructions

`msgsndu`, `msgsnd`, `msgsndp`, `msgclru`, `msgclr`, and `msgclrp` instructions are provided for sending and clearing messages. `msgsnc` is provided to enable the thread that is target of a `msgsndu` or `msgsnd` instruction to ensure that stores performed by the message-sending thread before it executed `msgsndu` or `msgsnc` have been performed with respect to the target thread. `msgsndp` and `msgclrp` are privileged instructions; `msgsnd`, `msgclru`, and `msgsnc` are hypervisor privileged instructions; `msgsndu` and `msgclrp` are ultravisor privileged instructions.

**Message Send Ultravisor X-form**

10 The message is sent to all threads on the same multi-threaded processor as the thread for which PIR44:63 is equal to the value of the PROCIDTAG field in the message payload.

11 Reserved

39:43 Reserved

44:63 PROCIDTAG

This field indicates the recipient thread(s) as specified in the B field. If this field set to a value that is not the same as bits PIR44:63 of any thread in the system, then the instruction behaves as if it were a no-op.

The actions taken on receipt of a message are defined in Section 11.2.

This instruction is ultravisor privileged.

**Special Registers Altered:**

None

**Programming Note**

If `msgsndu` is used to notify the receiver that updates have been made to storage, a `sync` should be placed between the stores and the `msgsndu`. See Section 6.9.2.
**Message Clear Ultravisor**

\[ \text{msgclru} \hspace{1em} \text{RB} \]

- \( t \) is set to hypervisor thread number of executing thread
- if \((\text{msgtype} = 0x05)\) then
  - clear any Directed Ultravisor Doorbell exception for thread \( t \)

\textit{msgclru} clears a message previously accepted by the thread executing the \textit{msgclru}.

Let \( \text{msgtype} \) be \((\text{RB})_{32:36}\), and let \( t \) be the hypervisor thread number of the thread executing the \textit{msgclru} instruction.

If \( \text{msgtype} = 0x05 \), then clear any Directed Ultravisor Doorbell exception that exists on thread \( t \); otherwise, this instruction is treated as a no-op.

This instruction is ultravisor privileged.

**Special Registers Altered:**

- None

---

**Programming Note**

\textit{msgclru} is typically issued only when MSR\_EE=0. If \textit{msgclru} is executed when MSR\_EE=1 when a Directed Ultravisor Doorbell interrupt is about to occur, the corresponding interrupt may or may not occur.

**Message Send**

\[ \text{msgsnd} \hspace{1em} \text{RB} \]

- \( \text{msgtype} \) is set to \( \text{GPR}(\text{RB})_{32:36} \)

    - 10 The message is sent to all threads on the same multi-threaded processor as the thread for which PIR\_44:63 is equal to the value of the PROCIDTAG field in the message payload.
    - 11 Reserved
  - 39:43 Reserved
  - 44:63 PROCIDTAG
    - This field indicates the recipient thread(s) as specified in the B field. If this field set to a
value that is not the same as bits PIR44:63 of any thread in the system, then the instruction behaves as if it were a no-op.

The actions taken on receipt of a message are defined in Section 11.2.

This instruction is hypervisor privileged.

**Special Registers Altered:**
None

**Programming Note**

If `msgsnd` is used to notify the receiver that updates have been made to storage, a `sync` should be placed between the stores and the `msgsnd`. See Section 6.9.2.

---

### Message Clear

`msgclr` clears a message previously accepted by the thread executing the `msgclr`.

Let `msgtype` be (RB)32:36, and let `t` be the hypervisor thread number of the thread executing the `msgclr` instruction.

If `msgtype` = 0x05, then clear any Directed Hypervisor Doorbell exception that exists on thread `t`; otherwise, this instruction is treated as a no-op.

This instruction is hypervisor privileged.

**Special Registers Altered:**
None

**Programming Note**

`msgclr` is typically issued only when MSR_EE=0. If `msgclr` is executed when MSR_EE=1 when a Directed Hypervisor Doorbell interrupt is about to occur, the corresponding interrupt may or may not occur.
**Message Send Privileged X-form**

```
msgsndp  RB
0 31  ///  /// RB 142 ///
```

```
msgtype ← (RB)32:36
payload ← (RB)37:63
t ← (RB)57:63
if msgtype = 5 and 
t ≤ maximum privileged thread number 
on processor or sub-processor 
then
  DPDES63 ← 1
  send_msg(msgtype, payload, t)
```

`msgsndp` sends a message to other threads that are on the same multi-threaded processor (if the processor is not in sub-processor mode) or to other threads that are on the same sub-processor (if the processor is in sub-processor mode). The message type and destination thread(s) are specified in RB.

**RB**

```
Message Payload
/// TYPE /// TIRTAG
0 32 37 39 57 63
```

**Figure 90. RB Contents for `msgsndp`**

The contents of RB are defined below. Bits 37:63 are referred to as the message payload.

**Bits Description**

- **37:56** Reserved
- **57:63** TIRTAG

This message is sent to the thread for which the privileged thread number is equal to contents of the TIRTAG field of the message payload, and one of the following conditions applies:

- for processors that are not partitioned into sub-processors, the thread is sent to the thread on the same multi-threaded processor for which the privileged thread number is equal to the contents of the TIRTAG field of the message payload.
- for processors that are partitioned into sub-processors, the thread is sent to the thread on the same sub-processor for which the privileged thread number is equal to the contents of the TIRTAG field of the message payload.

If `msgsndp` is executed with TIRTAG set to a value greater than the highest privileged thread number on the sub-processor (or on the multi-threaded processor if sub-processors are not supported), then this instruction behaves as a no-op.

The actions taken on receipt of a message are defined in Section 11.2.

This instruction is privileged.

**Special Registers Altered:**

- DPDES

**Programming Note**

If `msgsndp` is used to notify the receiver that updates have been made to storage, a `lwsync` or `sync` should be placed between the stores and the `msgsndp`. See Section 6.9.2.
Message Clear Privileged   X-form

msgclrp | RB
--- | ---
31 | /// | /// | RB | 174 | ///
0 | 8 | 11 | 16 | 21 | 31

msgclrp clears a message previously accepted by the thread executing the msgclrp.

Let msgtype be (RB)_{32:36}, and let t be the privileged thread number of the thread executing the msgclrp.

If msgtype = 0x05, then clear any Directed Privileged Doorbell exception that exists on thread t by setting DPDES_{63-t} to 0; otherwise, this instruction is treated as a no-op.

This instruction is privileged.

Special Registers Altered:

- DPDES

Programming Note

msgclrp is typically issued only when MSR_{EE}=0. If msgclrp is executed when MSR_{EE}=1 when a Directed Hypervisor Doorbell interrupt is about to occur, the corresponding interrupt may or may not occur.

Message Synchronize   X-form

msgsync

0 | /// | /// | /// | 886 | ///
0 | 8 | 11 | 16 | 21 | 31

In conjunction with the Synchronize and msgsnd or msgsndu instructions, the msgsync instruction provides an ordering function for stores that have been performed with respect to the thread executing the Synchronize and msgsnd or msgsndu instructions, relative to data accesses by other threads that are performed after a Directed Ultravisor Doorbell or Directed Hypervisor Doorbell interrupt has occurred, as described in the Synchronize instruction description on p. 1218.

This instruction is hypervisor privileged.

Special Registers Altered:

- None

Programming Note

When used in conjunction with msgsndu or msgsnd, Synchronize with L = 0 or 2 is executed on the thread that will execute the msgsndu or msgsnd, and msgsync is executed on another thread -- typically the thread that is the target of the msgsndu or msgsnd, but possibly any other thread (partly because the software that services the Directed Ultravisor Doorbell or Directed Hypervisor Doorbell interrupt may ultimately run on a thread other than that which received the exception). The Synchronize precedes the msgsndu or msgsnd, the msgsync is executed after the Directed Ultravisor Doorbell or Directed Hypervisor Doorbell interrupt occurs, and precedes all instructions that need to "see" the values stored by the stores that are in set A of the memory barrier created by the Synchronize; see Section 6.9.2, "Synchronize Instruction".
Chapter 12. Synchronization Requirements for Context Alterations

Changing the contents of certain System Registers, the contents of SLB entries, or the contents of other system resources that control the context in which a program executes can have the side effect of altering the context in which data addresses and instruction addresses are interpreted, and in which instructions are executed and data accesses are performed. For example, changing MSRIR from 0 to 1 has the side effect of enabling translation of instruction addresses. These side effects need not occur in program order, and therefore may require explicit synchronization by software. (Program order is defined in Book II.)

An instruction that alters the context in which data addresses or instruction addresses are interpreted, or in which instructions are executed or data accesses are performed, is called a context-altering instruction. This chapter covers all the context-altering instructions. The software synchronization required for them is shown in Table 7 (for data access) and Table 8 (for instruction fetch and execution).

The notation “CSI” in the tables means any context synchronizing instruction (e.g., sc, isync, or rfid). A context synchronizing interrupt (i.e., any interrupt except non-recoverable System Reset or non-recoverable Machine Check) can be used instead of a context synchronizing instruction. If it is, phrases like “the synchronizing instruction”, below, should be interpreted as meaning the instruction at which the interrupt occurs. If no software synchronization is required before (after) a context-altering instruction, “the synchronizing instruction before (after) the context-altering instruction” should be interpreted as meaning the context-altering instruction itself.

The synchronizing instruction before the context-altering instruction ensures that all instructions up to and including that synchronizing instruction are fetched and executed in the context that existed before the alteration. The synchronizing instruction after the context-altering instruction ensures that all instructions after that synchronizing instruction are fetched and executed in the context established by the alteration. Instructions after the first synchronizing instruction, up to and including the second synchronizing instruction, may be fetched or executed in either context.

If a sequence of instructions contains context-altering instructions and contains no instructions that are affected by any of the context alterations, no software synchronization is required within the sequence.

### Programming Note

Sometimes advantage can be taken of the fact that certain events, such as interrupts, and certain instructions that occur naturally in the program, such as the rfid that returns from an interrupt handler, provide the required synchronization.

Because the instructions between the first synchronizing instruction (exclusive) and the second synchronizing instruction (inclusive) may be fetched or executed in either context, if the context alteration affects whether the second synchronizing instruction can be fetched or executed then the context alteration will not necessarily be synchronized in the manner the programmer expected. For example, if the second synchronizing instruction is in a different virtual page from the context-altering instruction, and fetching instructions from this virtual page is prohibited by Virtual Page Class Key Storage Protection, and the context-altering instruction is an mtiamr that enables fetching instructions from this virtual page, it is indeterminate whether the second synchronizing instruction will be executed or a [Hypervisor] Instruction Storage interrupt will occur instead.

No software synchronization is required before or after a context-altering instruction that is also context synchronizing or when altering the MSR in most cases (see the tables). No software synchronization is required before most of the other alterations shown in Table 8, because all instructions preceding the context-altering instruction are fetched and decoded before the context-altering instruction is executed (the hardware must determine whether any of these preceding instructions are context synchronizing).

Unless otherwise stated, the material in this chapter assumes a single-threaded environment.

Table 8: Synchronization requirements for instruction fetch and/or execution
Notes:

1. The effect of changing the EE bit is immediate, even if the mtmsr[d] instruction is not context synchronizing (i.e., even if L=1).
   - If an mtmsr[d] instruction sets the EE bit to 0, neither an External interrupt, a Decrementer interrupt nor a Performance Monitor interrupt occurs after the mtmsr[d] is executed.
   - If an mtmsr[d] instruction changes the EE bit from 0 to 1 when an External, Decrementer, Performance Monitor or higher priority exception exists, the corresponding interrupt occurs immediately after the mtmsr[d] is executed, and before the next instruction is executed in the program that set EE to 1.
   - If a hypervisor executes the mtmsr[d] instruction that sets the EE bit to 0, a Hypervisor Decrementer interrupt does not occur after mtmsr[d] is executed as long as the thread remains in hypervisor state.
   - If the hypervisor executes an mtmsr[d] instruction that changes the EE bit from 0 to 1 when a Hypervisor Decrementer or higher priority exception exists, the corresponding interrupt occurs immediately after the mtmsr[d] instruction is executed, and before the next instruction is executed, provided HDICE is 1.

2. Synchronization requirements for this instruction are implementation-dependent.

3. The PTCR controls all implicit and explicit storage accesses performed by all threads on the processor when the thread is not in hypervisor or ultravisor real addressing mode. Modifying the PTCR requires that the following conditions be achieved on all threads on the processor:
   - the thread is in hypervisor or ultravisor real addressing mode
   - all previous accesses (implicit and explicit) initiated when the thread was not in hypervisor or ultravisor real addressing mode have been performed with respect to all threads
   - no subsequent accesses which require translation have been initiated

4. For data accesses, the context synchronizing instruction before the slbie, slbief, slbia, slbmt, tlbie, or tlbief instruction ensures that all preceding instructions that access data storage have completed to a point at which they have reported all exceptions they will cause.

The context synchronizing instruction after the slbie, slbief, slbia, tlbie or tlbief instruction ensures that storage accesses associated with instructions following the context synchronizing instruction will not use the SLB entry(s), TLB entry(s), or implementation-specific lookaside information being invalidated.

(For tlbief and tlbie, if it is necessary to order storage accesses associated with preceding instructions, or Reference and Change bit updates associated with preceding address translations, with respect to subsequent data accesses, a ptesync instruction must also be used, either before or after the tlbie or tlbief instruction. These effects of the ptesync instruction are described in the last paragraph of Note 5.)

5. The notation “(ptesync,CSI)” denotes an instruction sequence. Other instructions may be interleaved with this sequence, but these instructions must appear in the order shown.

No software synchronization is required before the Store instruction because (a) stores are not performed out-of-order and (b) address translations associated with instructions preceding the Store instruction are not performed again after the store has been performed (see Section 6.5). These properties ensure that all address translations associated with instructions preceding the Store instruction will be performed using the old contents of the PTE.

The ptesync instruction after the Store instruction ensures that all searches of the Page Table that are performed after the ptesync instruction completes will use the value stored (or a value stored subsequently). The context synchronizing instruction after the ptesync instruction ensures that any address translations associated with instructions following the context synchronizing instruction that were performed using the old contents of the PTE will be discarded, with the result that these address translations will be performed again and, if there is no corresponding entry in any TLB, SLB, page walk cache, cache of Partition or Process Table entries, or implementation-specific address translation lookaside information, will use the value stored (or a value stored subsequently).

The ptesync instruction also ensures that all storage accesses associated with instructions preceding the ptesync instruction, and all Reference and Change bit updates associated with additional address translations that were performed, by the thread executing the ptesync instruction, before the ptesync instruction is executed, will be performed with respect to any thread or mechanism, to the extent required by the associated Memory Coherence Required attributes, before any data accesses caused by instructions following the ptesync instruction are performed with respect to that thread or mechanism.

6. There are additional software synchronization requirements for this instruction in multi-threaded environments (e.g., it may be necessary to invalidate one or more TLB entries on all threads in the system and to be able to determine that the invali-
versions have completed and that all side effects of the invalidations have taken effect).

Section 6.10 gives examples of using *tlbie*, *Store*, and related instructions to maintain the Page Table, in both multi-threaded environments and environments consisting of only a single-threaded processor.

--- Programming Note ---

In a multi-threaded system, if software locking is used to help ensure that the requirements described in Section 6.10 are satisfied, the *isync* instruction near the end of the lock acquisition sequence (see Section B.2.1.1 of Book II) may naturally provide the context synchronization that is required before the alteration.

7. The alteration must not cause an implicit branch in effective address space. Thus, when changing MSR_SF from 1 to 0, the *mtmsrd* instruction must have an effective address that is less than $2^{32} - 4$. Furthermore, when changing MSR_SF from 0 to 1, the *mtmsrd* instruction must not be at effective address $2^{32} - 4$ (see Section 6.3.2 on page 1177).

8. The alteration must not cause an implicit branch in real address space. Thus the real address of the context-altering instruction and of each subsequent instruction, up to and including the next context synchronizing instruction, must be independent of whether the alteration has taken effect.

--- Programming Note ---

If it is desired to set MSR_{IR} to 1 early in an operating system interrupt handler, advantage can sometimes be taken of the fact that EA_{0,3} are ignored when forming the real address when address translation is disabled and MSR_{AV} = 0. For example, if address translation resources are set such that effective address 0x0000_0000_0000_0000 maps to real address 0x0000_0000_0000_0000 when address translation is enabled, where n is an arbitrary 4-bit value, the following code sequence, in real page 0, can be used early in the interrupt handler.

```
  la   rx,target
  li   ry,0xn000
  sldi ry,ry,48
  or   rx,rx,ry  # set high-order nibble of target addr to 0xn
  mtctr rx
  bcctr # branch to target
```

targ:  mfsr  rx
      orir x,rx,0x0020
      mtmsrd rx  # set MSR_{IR} to 1

The *mtmsrd* does not cause an implicit branch in real address space because the real address of the next sequential instruction is independent of MSR_{IR}. Using *mtmsrd*, rather than *rfid* (or similar context synchronizing instruction that alters the control flow), may yield better performance on some implementations.

(Variations on the technique are possible. For example, the target instruction of the *bcctr* can be in arbitrary real page P, where P is a 48-bit value, provided that effective address 0xn || P || 0x000 maps to real address P || 0x000 when address translation is enabled.)

9. The elapsed time between the contents of the Decrementer or Hypervisor Decrementer becoming negative and the signaling of the corresponding exception is not defined.

10. If an *slbme* instruction alters the mapping, or associated attributes, of a currently mapped ESID, the *slbme* must be preceded by an *slbie* (or *slbia*) instruction that invalidates the existing translation. This applies even if the corresponding entry is no longer in the SLB (the translation may still be in implementation-specific address translation lookaside information). No software synchronization is needed between the *slbie* and the *slbme*, regardless of whether the index of the SLB entry (if any) containing the current translation is the same as the SLB index specified by the *slbme*.
No `%slbme` is needed if the `%slbme` instruction replaces a valid SLB entry with a mapping of a different ESID (e.g., to satisfy an SLB miss). However, the `%slbie` is needed later if and when the translation that was contained in the replaced SLB entry is to be invalidated.

11. When the URMOR or the HRMOR is modified, software must invalidate all implementation-specific lookaside information used in address translation that depends on the old contents of the register (i.e., the contents immediately before the modification). The `%slbie` instruction can be used to invalidate all such implementation-specific lookaside information.

12. A context synchronizing instruction or event that is executed or occurs when LPCR MER = 1 does not necessarily ensure that the exception effects of LPCRMER are consistent with the contents of LPCRMER. See Section 2.2.

13. This line applies regardless of which SPR number (13 or 29) is used for the AMR.

14. LPIDR when using HPT translation and LPCRHR must not be altered when MSRDR=1 or MSRIR=1; if they are, the results are undefined.

--- Programming Note ---

For instruction fetch, the prohibitions above are because of the difficulty of avoiding an implicit branch relative to the value of enabling software to avoid using hypervisor real addressing mode for the operation. For data access, the prohibitions above are to avoid errant (wrongly timed and/or for an incorrect context) speculative translation in support of hardware data prefetching. (The tables used for translation are determined by the partition ID and LPCRHR is used as a shortcut. See Section 6.7.6 for details.)

15. This line applies to the following Performance Monitor SPRs: PMC1-6, MMCR0, MMCR1, MMCR2, and MMCRA.

16. This line applies to all SPR numbers that access the BESCR (800-803, 806).

17. There are additional software synchronization requirements when an `%mtspr` instruction modifies this SPR in a multi-threaded environment. See Section 2.7.

18. As an alternative to a CSI, the execution of an `%rfebb` instruction or the occurrence of an event-based branch is sufficient to provide the necessary synchronization.

19. When LPCR ISL or PATE PS is modified, software must invalidate all implementation-specific lookaside information used in address translation that depends on the old contents of the field (i.e., the contents immediately before the modification). The `%slbie` instruction can be used to invalidate all such implementation-specific lookaside information.

20. `%hwsync` (or `%ptesync`) is required between the last instruction that causes a storage access (e.g., Load, Store, `dcbz`) for which the EA was translated using the current contents of LPIDR and/or PIDR and a subsequent `%mtlpidr` and/or `%mtpidr` that changes the LPID and/or PID value.

--- Programming Note ---

The preceding requirement permits designs to optimize `%tlbie` processing when the LPID and PID values specified by the `%tlbie` differ from those in effect on the receiving thread, by ensuring that all storage accesses that were caused by preceding instructions and for which the EA was translated using the current contents of LPIDR and PIDR have been performed with respect to all threads before the contents of these registers are changed.
Power ISA Book I-III Appendices
Appendix A. Notes on the Removal of Transactional Memory from the Architecture

Facilities that are available in problem state are generally not removed from the architecture because of the potential impact to the code base. Transactional Memory is a special case in that the major operating environments require software to check the availability of the facility prior to using it. In addition, the requirement that every transaction have a failure handler means that any application that uses TM will continue to function on a degenerate TM implementation that simply fails each transaction on the instruction that follows \texttt{tbegm}. These two facts enable a minimally-disruptive ecosystem transition to remove TM, even while continuing to provide product features such as live partition migration.

The anticipated system support for the removal of TM uses a \textit{synthetic} TM implementation when the thread is running in “Version 3.0 mode” (PCR\textsubscript{3.0} v2=0b10) or in “Version 2.07 mode” (PCR\textsubscript{3.0} v2=0b11). (See Section 2.5 of Book III.) For partitions running in “Version 3.1 mode” (PCR\textsubscript{3.0} v2=0b00), hypervisor software disables TM by setting HFSCR\textsubscript{58} (formerly the Transactional Memory Facility bit) to zero, and then ensures that the thread will always be in Non-transactional state by setting MSR\textsubscript{29:30} (formerly the Transaction State field) to 0b00 before dispatching the partition. (The latter requirement will be satisfied naturally provided that the hypervisor executes \texttt{treclaim}, as part of context switch, as required in Versions 2.07B and 3.0C of the architecture.)

Synthetic TM is required in order to provide unrestricted live migration of partitions running in PCR modes that supported TM (PCR\textsubscript{3.0}=1). The TM architecture allowed for access to TM SPRs and execution of TM instructions even in Non-transactional state, making pure, interrupt-driven emulation too great a performance risk. Instead, processor implementations provide default behaviors for TM-related operations. Each new transaction fails on the instruction after \texttt{tbegm}, going immediately to the failure handler. (Failure recording for this special case sets the Failure Persistent bit in TEXASR to reduce the likelihood that software will pointlessly retry the transaction, and also sets the Implementation-specific cause bit in TEXASR.) \texttt{mtspr} and \texttt{mspr} for TM SPRs have their normal behavior. Most of the other TM instructions behave as they would have behaved in Non-transactional state -- i.e., just changing CR0 and FXCC. (See Book II Section 5.5 and Book III Section 5.4.4 in Version 3.0C for background on the TM instructions.) These are the behaviors that will be seen by most software. Thus, under synthetic TM, a thread is never productively in Transactional state, and is in Suspended state (actually, synthetic Suspended state) only if the program was migrated, while in Suspended state, from a processor that implements Version 3.0C or Version 2.07B. The handling for applications migrated while in Suspended state is beyond the scope of this explanation. See the implementation’s user manual for details.

The architecture proper portrays TM to be fully removed. The HFSCR is used to disable TM in Version 3.0 mode because it is impractical to give the appearance that TM has been entirely removed. When the thread is in problem state or privileged non-hypervisor state, the deviations from the behavior for complete removal will be what one would expect if TM was implemented but disabled by the HFSCR. The following sections describe deviations in Version 3.1 mode with HFSCR\textsubscript{58} set to zero from the behavior if TM was completely removed. The description is somewhat redundant in describing deviations both from the cause and effect points of view. It does not discuss deviations that can happen only in hypervisor state. The hypervisor and ultravisor must not use any resource formerly allocated to TM other than HFSCR\textsubscript{58}.

A.1 Attempted Execution of TM Instructions

Non-privileged TM instructions were encoded using primary opcode 31 with extended opcodes 654, 686, 718, 750, 782, 814, 846, 878, and 910. Privileged TM instructions were encoded using primary opcode 31 with extended opcodes 942 and 1006.

An attempt in privileged non-hypervisor state to execute a TM instruction, or an attempt in problem state to execute a non-privileged TM instruction, will cause a Hypervisor Facility Unavailable interrupt with HFSCR\textsubscript{IC} = 0x05 indicating that the cause was an attempt to use a TM resource. Since the architecture portrays the instructions as reserved, a Hypervisor Emulation Assistance interrupt would be expected. The hypervisor's
A.3 Occurrence of the Hypervisor Facility Unavailable Interrupt with \(\text{HFSCR}_{\text{IC}} = 0x05\)

A Hypervisor Facility Unavailable interrupt that set \(\text{HFSCR}_{\text{IC}}\) to 0x05 indicated an attempt to execute a TM instruction or to access a TM SPR when \(\text{HFSCR}_{38}\) is set to zero. Despite that the architecture no longer includes Transactional Memory, this variant of the Hypervisor Facility Unavailable interrupt will occur in the circumstances described in the previous two sections and should be handled as described there.

A.4 Occurrence of the TM Bad Thing Type Program Interrupt

A Program interrupt that set \(\text{SRR1}_{42}\) to 1 indicated a TM Bad Thing type Program interrupt. Despite that the architecture no longer includes Transactional Memory, this variant of Program interrupt will occur as the result of an attempt to set \(\text{MSR}_{29:30}\) to a value other than 0b00 via an \(\text{mmsrd}\) or a “return from”-type instruction, including \(\text{rfebb}\). These bits had indicated the Transaction State. As they are now reserved, the Program interrupt would be unanticipated. Because the connection between the BESCR and the MSR bits is especially hard to make without referencing previous versions of the architecture, the forms of \(\text{rfebb}\) that set \(\text{MSR}_{29:30}\) to a value other than 0b00 are specified to be treated as though the instruction form is invalid. If a Program interrupt occurs from problem state with \(\text{SRR1}_{42} = 1\), the Program interrupt handler should treat the offending instruction as an illegal instruction.

A.5 Failure of Performance Monitor Counters to Count

\(\text{MMCR0}_{47}\) was formerly the Freeze Counters in Non-Transactional State bit. Despite the architecture’s portrayal of this bit as reserved, a 1 value in this bit will prevent Performance Monitor Counters from counting their assigned events. Software should set \(\text{MMCR0}_{47}\) to zero.

A.6 Behavior of SPR Bits Formerly Related to TM

Aside from handling the bits formerly related to TM as described above, a good general rule is to practice read-modify-write on the containing SPRs for TM-related bits, leaving their values unchanged. Software is generally permitted to write reserved bits with the expectation, in privileged state, of reading back the written value if the bit is implemented in hardware and
with the expectation that the bit will be ignored by hardware. Capriciously setting the relevant bits in SRR1, the CTR, or directly in the MSR may have the result discussed in Section A.4. Beyond this, the deviations take the form of hardware occasionally setting bits, such as the bits that were formerly MSR\textsubscript{TM} and BESC\textsubscript{TS}, to zero.
Appendix B. Illegal Instructions

With the exception of the instruction consisting entirely of binary 0s, the instructions in this class are available for future extensions of the Power ISA; that is, some future version of the Power ISA may define any of these instructions to perform new functions.

The following primary opcodes are illegal.

5

The following primary opcode is used for an instruction prefix.

1

The following primary opcodes have unused extended opcodes. Their unused extended opcodes can be determined from the opcode maps in Appendix D of Book Appendices. All unused extended opcodes are illegal.

4, 6, 19, 30, 3156, 58, 59, 60, 62, 63

The following primary+extended opcodes have unused expanded opcodes. Their unused expanded opcodes can be determined from the opcode maps in Appendix C of Book Appendices. All unused expanded opcodes are illegal.

primary / extended opcode

4 / 0b10110_000001
4 / 0b11110_000001
4 / 0b11000_000010
60 / 0b01011_01000.
60 / 0b10101_1011.. 
60 / 0b11101_1011.. 
63 / 0b10010_00100.
63 / 0b11010_00100.
63 / 0b10010_00111.

An instruction consisting entirely of binary 0s is illegal, and is guaranteed to be illegal in all future versions of this architecture.
Appendix C. Reserved Instructions

The instructions in this class are allocated to specific purposes that are outside the scope of the Power ISA.

The following types of instruction are included in this class.

1. The instruction having primary opcode 0, except the instruction consisting entirely of binary 0s (which is an illegal instruction; see Section 1.7.2, "Illegal Instruction Class" on page 24) and the extended opcode shown below.

   **256**  Service Processor "Attention"

2. Instructions from the POWER Architecture that have not been included in the Power ISA.

3. Instructions defined in a previous version of the Power ISA that have been removed.

4. Implementation-specific instructions used to conform to the Power ISA specification.

5. Any other implementation-dependent instructions that are not defined in the Power ISA.
This appendix contains opcode maps showing the primary opcodes, extended opcodes, and expanded opcodes. Table 9 describes the conventions used in the opcode maps.

Table 9: Opcode Maps Legend

<table>
<thead>

</tr>
</tbody>
</table>

- **po** primary opcode (decimal format)
- **xop** extended or expanded opcode image (binary format)
  - 0 instruction bit corresponding to an extended/expanded opcode bit having value of 0
  - 1 instruction bit corresponding to an extended/expanded opcode bit having value of 1
  - reserved instruction bit, must have value of 0, otherwise invalid form
  - . instruction bit corresponding to an operand or control bit, can have a value of either 0 or 1

**book**
- Book instruction defined

**version**
- ISA version instruction introduced

**privilege**
- P privileged instruction
- HV hypervisor-privileged instruction
- UV ultravisor-privileged instruction

**format**
- instruction format

**Illegal opcode**
- Opcode having no previous or current assignment, available for future use

**Defined opcode (primary, extended, or expanded)**
- Opcode assigned to a defined instruction

**Primary opcode having an extended opcode field**
- Opcode having extended opcode field used to identify multiple instructions

**Extended opcode having an expanded opcode field**
- Opcode having expanded opcode field used to identify multiple instructions

**Reserved opcode (primary, extended, or expanded)**
- Opcode is not available for future use without careful consideration
  1. Opcode corresponds to an instruction defined in a previous version of the architecture that has been subsequently removed from the architecture. The opcode is treated as an illegal opcode.
  2. Or, opcode is reserved for implementation-dependent use.
- These opcodes will not be assigned a meaning in the Power ISA except after careful consideration of the effect of such assignment on existing implementations.

**Invalid form opcode**
- Opcode corresponding to a defined instruction encoding with one or more reserved opcode bits having a value of 1
Table 10: Primary Opcode Map for Opcode Space 0 (32-bit instruction encoding) (bits 0-5)
Primary opcodes of word instructions are mapped to opcode space 0
Primary opcodes of suffixes of M[M](LS)RR-form prefixed instructions are mapped to opcode space 0

### Appendix E. Power ISA Instruction Set Sorted by Opcode

This appendix lists all the instructions in the Power ISA, sorted by primary opcode (bits 0-5), then by extended opcode column (bits 26:31, if any), then by extended opcode row (bits 21:25, if any), then by expanded opcode (bits 11:15, if any).

### Figure 91. Power ISA AS Instruction Set Sorted by Opcode (Sheet 30 of 30)

1. **Instruction**
   - Instruction bit that corresponds to a reserved field, must have a value of 0, otherwise invalid form.
   - Instruction bit that corresponds to an operand bit, may have a value of either 0 or 1.
   - Instruction bit that corresponds to an opcode bit having a value 0.
   - Instruction bit that corresponds to an opcode bit having a value 1.

2. **OpenPOWER Compliancy Subsets**
   - X... Instruction included in the Scalar Fixed-Point Compliancy subset.
   - .X.. Instruction included in the Scalar Fixed-Point + Floating-Point Compliancy subset.
   - ..X. Instruction included in the Linux Compliancy subset.
   - ...X Instruction included in the AIX Compliancy subset.

3. **Linux Optional Category**
   - AMO Instruction part of Atomic Memory Operations category.
   - BFP128 Instruction part of Quad-Precision Floating-Point category.
   - BHRB Instruction part of Branch History Rolling Buffer category.
   - DFP Instruction part of Decimal Floating-Point category.
   - EBB Instruction part of Event-Based Branch category.
   - MMA Instruction part of Matrix-Multiplication Assist category.

4. **Always Optional Category**
   - MMA Instruction part of Matrix-Multiplication Assist category.

5. **Version**
   - P1 Instruction introduced in POWER Architecture.
   - P2 Instruction introduced in POWER2 Architecture.
   - PPC Instruction introduced in PowerPC Architecture prior to v2.00.
   - v2.00 Instruction introduced in PowerPC Architecture Version 2.00.
   - v2.01 Instruction introduced in PowerPC Architecture Version 2.01.
   - v2.02 Instruction introduced in PowerPC Architecture Version 2.02.
   - v2.03 Instruction introduced in Power ISA Version 2.03.
   - v2.04 Instruction introduced in Power ISA Version 2.04.
   - v2.05 Instruction introduced in Power ISA Version 2.05.
   - v2.06 Instruction introduced in Power ISA Version 2.06.
   - v2.07 Instruction introduced in Power ISA Version 2.07.
   - v3.0 Instruction introduced in Power ISA Version 3.0.
   - v3.0B Instruction introduced in Power ISA Version 3.0B.
   - v3.0C Instruction introduced in Power ISA Version 3.0C.
   - v3.1 Instruction introduced in Power ISA Version 3.1.
### 6. Privilege

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>P</td>
<td>Denotes an instruction that is treated as privileged.</td>
</tr>
<tr>
<td>O</td>
<td>Denotes an instruction that is treated as privileged or nonprivileged (or hypervisor-privileged for mtspr), depending on the SPR or PMR number.</td>
</tr>
<tr>
<td>PI</td>
<td>Denotes an instruction that is illegal in privileged state.</td>
</tr>
<tr>
<td>HV</td>
<td>Denotes an instruction that can be executed only in hypervisor state.</td>
</tr>
<tr>
<td>UV</td>
<td>Denotes an instruction that can be executed only in ultravisor state.</td>
</tr>
</tbody>
</table>

### 7. Mode Dependency

Except as described below and in Section 1.10.3, “Effective Address Calculation”, in Book I, all instructions are independent of whether the processor is in 32-bit or 64-bit mode.

- **CT**: If the instruction tests the Count Register, it tests the low-order 32 bits in 32-bit mode and all 64 bits in 64-bit mode.
- **SR**: The setting of status registers (such as XER and CR0) is mode-dependent.
- **SF=1**: The instruction can be executed only in 64-bit mode.
Appendix F. Power ISA Instruction Set Sorted by Version

This appendix lists all the instructions in the Power ISA, sorted in reverse order by ISA version, then by mnemonic.

1. Instruction

1 Instruction bit that corresponds to a reserved field, must have a value of 0, otherwise invalid form.
0 Instruction bit that corresponds to an operand bit, may have a value of either 0 or 1.
1 Instruction bit that corresponds to an opcode bit having a value 0.
0 Instruction bit that corresponds to an opcode bit having a value 1.

2. OpenPOWER Compliancy Subsets

X... Instruction included in the Scalar Fixed-Point Compliancy subset
.X.. Instruction included in the Scalar Fixed-Point + Floating-Point Compliancy subset.
..X. Instruction included in the Linux Compliancy subset.
...X Instruction included in the AIX Compliancy subset.

3. Linux Optional Category

AMO Instruction part of Atomic Memory Operations category.
BFP128 Instruction part of Quad-Precision Floating-Point category.
BHRB Instruction part of Branch History Rolling Buffer category.
DFP Instruction part of Decimal Floating-Point category.
EBB Instruction part of Event-Based Branch category.
MMA Instruction part of Matrix-Multiplication Assist category.

4. Always Optional Category

MMA Instruction part of Matrix-Multiplication Assist category.

5. Version

P1 Instruction introduced in POWER Architecture.
P2 Instruction introduced in POWER2 Architecture.
PPC Instruction introduced in PowerPC Architecture prior to v2.00.
v2.00 Instruction introduced in PowerPC Architecture Version 2.00.
v2.01 Instruction introduced in PowerPC Architecture Version 2.01.
v2.02 Instruction introduced in PowerPC Architecture Version 2.02.
v2.03 Instruction introduced in Power ISA Version 2.03.
v2.04 Instruction introduced in Power ISA Version 2.04.
v2.05 Instruction introduced in Power ISA Version 2.05.
v2.06 Instruction introduced in Power ISA Version 2.06.
v2.07 Instruction introduced in Power ISA Version 2.07.
v3.0 Instruction introduced in Power ISA Version 3.0.
v3.0B Instruction introduced in Power ISA Version 3.0B.
v3.0C Instruction introduced in Power ISA Version 3.0C.
v3.1 Instruction introduced in Power ISA Version 3.1.

6. Privilege

P Denotes an instruction that is treated as privileged.
O Denotes an instruction that is treated as privileged or nonprivileged (or hypervisor-privileged for mtspr), depending on the SPR or PMR number.
PI Denotes an instruction that is illegal in privileged state.
HV Denotes an instruction that can be executed only in hypervisor state.
UV Denotes an instruction that can be executed only in ultravisor state.
7. **Mode Dependency.**

Except as described below and in Section 1.10.3, "Effective Address Calculation", in Book I, all instructions are independent of whether the processor is in 32-bit or 64-bit mode.

- **CT** If the instruction tests the Count Register, it tests the low-order 32 bits in 32-bit mode and all 64 bits in 64-bit mode.
- **SR** The setting of status registers (such as XER and CR0) is mode-dependent.
- **SF=1** The instruction can be executed only in 64-bit mode.
Appendix G. Power ISA Instruction Set Sorted by OpenPOWER Compliancy Subset

This appendix lists all the instructions in the Power ISA, sorted by the instruction’s OpenPOWER compliancy subset membership, then by mnemonic.

### 1. Instruction
- /: Instruction bit that corresponds to a reserved field, must have a value of 0, otherwise invalid form.
- #: Instruction bit that corresponds to an operand bit, may have a value of either 0 or 1.
- $: Instruction bit that corresponds to an opcode bit having a value 0.
- #: Instruction bit that corresponds to an opcode bit having a value 1.

### 2. OpenPOWER Compliancy Subsets
- X..: Instruction included in the Scalar Fixed-Point Compliancy subset
- .X.: Instruction included in the Scalar Fixed-Point + Floating-Point Compliancy subset.
- ..X.: Instruction included in the Linux Compliancy subset.
- ...X: Instruction included in the AIX Compliancy subset.

### 3. Linux Optional Category
- AMO: Instruction part of Atomic Memory Operations category.
- BFP128: Instruction part of Quad-Precision Floating-Point category.
- BHRB: Instruction part of Branch History Rolling Buffer category.
- DFP: Instruction part of Decimal Floating-Point category.
- EBB: Instruction part of Event-Based Branch category.
- MMA: Instruction part of Matrix-Multiplication Assist category.

### 4. Always Optional Category
- MMA: Instruction part of Matrix-Multiplication Assist category.
### 5. Version

- **P1**: Instruction introduced in POWER Architecture.
- **P2**: Instruction introduced in POWER2 Architecture.
- **PPC**: Instruction introduced in PowerPC Architecture prior to v2.00.
- **v2.00**: Instruction introduced in PowerPC Architecture Version 2.00.
- **v2.01**: Instruction introduced in PowerPC Architecture Version 2.01.
- **v2.02**: Instruction introduced in PowerPC Architecture Version 2.02.
- **v2.03**: Instruction introduced in Power ISA Version 2.03.
- **v2.04**: Instruction introduced in Power ISA Version 2.04.
- **v2.05**: Instruction introduced in Power ISA Version 2.05.
- **v2.06**: Instruction introduced in Power ISA Version 2.06.
- **v2.07**: Instruction introduced in Power ISA Version 2.07.
- **v3.0**: Instruction introduced in Power ISA Version 3.0.
- **v3.0B**: Instruction introduced in Power ISA Version 3.0B.
- **v3.0C**: Instruction introduced in Power ISA Version 3.0C.
- **v3.1**: Instruction introduced in Power ISA Version 3.1.

### 6. Privilege

- **P**: Denotes an instruction that is treated as privileged.
- **O**: Denotes an instruction that is treated as privileged or nonprivileged (or hypervisor-privileged for mtspr), depending on the SPR or PMR number.
- **PI**: Denotes an instruction that is illegal in privileged state.
- **HV**: Denotes an instruction that can be executed only in hypervisor state.
- **UV**: Denotes an instruction that can be executed only in ultravisor state.

### 7. Mode Dependency

Except as described below and in Section 1.10.3, “Effective Address Calculation”, in Book I, all instructions are independent of whether the processor is in 32-bit or 64-bit mode.

- **CT**: If the instruction tests the Count Register, it tests the low-order 32 bits in 32-bit mode and all 64 bits in 64-bit mode.
- **SR**: The setting of status registers (such as XER and CR0) is mode-dependent.
- **SF=1**: The instruction can be executed only in 64-bit mode.
Appendix H. Power ISA Instruction Set Sorted by Mnemonic

This appendix lists all the instructions in the Power ISA, sorted by mnemonic.

Figure 94. Power ISA AS Instruction Set Sorted by Mnemonic (Sheet 29 of 30)
### Figure 94. Power ISA AS Instruction Set Sorted by Mnemonic (Sheet 30 of 30)

1. **Instruction**
   - `/` Instruction bit that corresponds to a reserved field, must have a value of 0, otherwise invalid form.
   - `. ` Instruction bit that corresponds to an operand bit, may have a value of either 0 or 1.
   - `0` Instruction bit that corresponds to an opcode bit having a value 0.
   - `1` Instruction bit that corresponds to an opcode bit having a value 1.

2. **OpenPOWER Compliancy Subsets**
   - `X...` Instruction included in the Scalar Fixed-Point Compliancy subset
   - `.X...` Instruction included in the Scalar Fixed-Point + Floating-Point Compliancy subset.
   - `.X...` Instruction included in the Linux Compliancy subset.
   - `...X` Instruction included in the AIX Compliancy subset.

3. **Linux Optional Category**
   - AMO Instruction part of Atomic Memory Operations category.
   - BFP128 Instruction part of Quad-Precision Floating-Point category.
   - BHRB Instruction part of Branch History Rolling Buffer category.
   - DFP Instruction part of Decimal Floating-Point category.
   - EBB Instruction part of Event-Based Branch category.
   - MMA Instruction part of Matrix-Multiplication Assist category.

4. **Always Optional Category**
   - MMA Instruction part of Matrix-Multiplication Assist category.

5. **Version**
   - P1 Instruction introduced in POWER Architecture.
   - P2 Instruction introduced in POWER2 Architecture.
   - PPC Instruction introduced in PowerPC Architecture prior to v2.00.
   - v2.00 Instruction introduced in PowerPC Architecture Version 2.00.
   - v2.01 Instruction introduced in PowerPC Architecture Version 2.01.
   - v2.02 Instruction introduced in PowerPC Architecture Version 2.02.
   - v2.03 Instruction introduced in Power ISA Version 2.03.
   - v2.04 Instruction introduced in Power ISA Version 2.04.
   - v2.05 Instruction introduced in Power ISA Version 2.05.
   - v2.06 Instruction introduced in Power ISA Version 2.06.
   - v2.07 Instruction introduced in Power ISA Version 2.07.
   - v3.0 Instruction introduced in Power ISA Version 3.0.
   - v3.0B Instruction introduced in Power ISA Version 3.0B.
   - v3.0C Instruction introduced in Power ISA Version 3.0C.
   - v3.1 Instruction introduced in Power ISA Version 3.1.

6. **Privilege**
   - `P` Denotes an instruction that is treated as privileged.
   - `O` Denotes an instruction that is treated as privileged or nonprivileged (or hypervisor-privileged for mtspr), depending on the SPR or PMR number.
   - `PI` Denotes an instruction that is illegal in privileged state.
   - `HV` Denotes an instruction that can be executed only in hypervisor state.
   - `UV` Denotes an instruction that can be executed only in ultravisor state.
7. **Mode Dependency.**

Except as described below and in Section 1.10.3, "Effective Address Calculation", in Book I, all instructions are independent of whether the processor is in 32-bit or 64-bit mode.

- **CT** If the instruction tests the Count Register, it tests the low-order 32 bits in 32-bit mode and all 64 bits in 64-bit mode.
- **SR** The setting of status registers (such as XER and CR0) is mode-dependent.
- **SF=1** The instruction can be executed only in 64-bit mode.
